Mineralocorticoids Any of the group of 21-carbon corticosteroids (principally aldosterone) that contribute to the regulation of (1) water, (2) acid-base, and (3) electrolyte balance in the body.

Renin A hydrolase enzyme that catalyzes cleavage of the leucine-leucine bond in angiotensinogen to generate angiotensin I.

Steroidogenesis The biosynthesis of steroids by the adrenal glands and gonads.

Steroidogenic acute regulatory protein (StAR) A transport protein that functions to regulate cholesterol transfer within the mitochondria.

Waterhouse-Friderichsen syndrome Adrenal gland failure caused by bleeding into the adrenal gland; it is a fulminating complication of bacterial infections, notably meningococcemia; characterized by sudden onset and short course, cyanosis with petechial hemorrhages of the skin and mucous membranes, fever, and hypotension that can lead to shock and coma.

Zona fasciculata The thick middle layer of the adrenal cortex that contains large lipid-laden cells. It is the major source of glucocorticoids and, to a lesser extent, adrenal androgens.

Zona glomerulosa The thin outer layer of the adrenal cortex. It is the source of mineralocorticoids.

Zona reticularis The inner layer of the adrenal cortex. Its cells resemble those of the zona fasciculata, except they contain less lipid. The zona reticularis is the major source of adrenal androgens and produces glucocorticoids to a lesser degree.

The adrenal gland lies at the upper pole of each human kidney (see Figure 25-1, Chapter 25, page 431). Each gland (1) is pyramidal in shape, (2) is approximately 2 to 3 cm in width, 4 to 6 cm long, 1 cm thick, and (3) weighs approximately 4 g, regardless of age, weight, or sex. Each gland consists of a yellow, outer cortex and a gray, inner medulla. Beneath the capsule of the outer cortex lies the **zona glomerulosa** that constitutes approximately 15% of the cortex (Table 41-1). The next layer is the **zona fasciculata** that composes about 75% of the cortex with large and lipid-laden cells. The innermost zone is the **zona reticularis** that contains irregular looking cells with little lipid content. The cells of the adrenal cortex synthesize steroid hormones. The cells of the adrenal medulla synthesize catecholamines, such as (1) dopamine, (2) norepinephrine, and (3) epinephrine aromatic amines, which have important consequences for blood pressure regulation. The catecholamines and their function are discussed in Chapter 26.

The human adrenal cortex secretes three major classes of steroid hormones that possess a wide range of physiological functions. These are the (1) **mineralocorticoids**, (2) **glucocorticoids**, and (3) **adrenal androgens**. This chapter begins with a section on general steroid biochemistry, followed by a discussion of the clinical and biological functions of the steroid hormones produced by the adrenal cortex.

General Steroid Chemistry

Steroid hormones are steroids that act as hormones. In this section, the general (1) chemical structure, (2) biochemistry, and (3) metabolism of steroids are briefly discussed.

Chemical Structure

Steroids contain a cyclopentanoperhydrophenanthrene nucleus as their basic structure (Figure 41-1). The three six-sided rings (A, B, and C) constitute the phenanthrene nucleus, to which is attached the D or cyclopentane ring. The prefix "perhydro" refers to the saturation of the compound with hydrogen atoms. This class of compounds includes such natural products as (1) sterols

TABLE 41-1 Anatomy and Products of the Adrenal Gland

Adrenal Layer	Major Product(s)	Action
Cortex		
Zona glomerulosa	Aldosterone	Mineralocorticoid
Zona fasciculata	Cortisol	Glucocorticoid
Zona reticularis	Dehydroepiandrosterone (DHEA)	Androgens
	Androstenedione	
Medulla	Epinephrine	Catecholamine

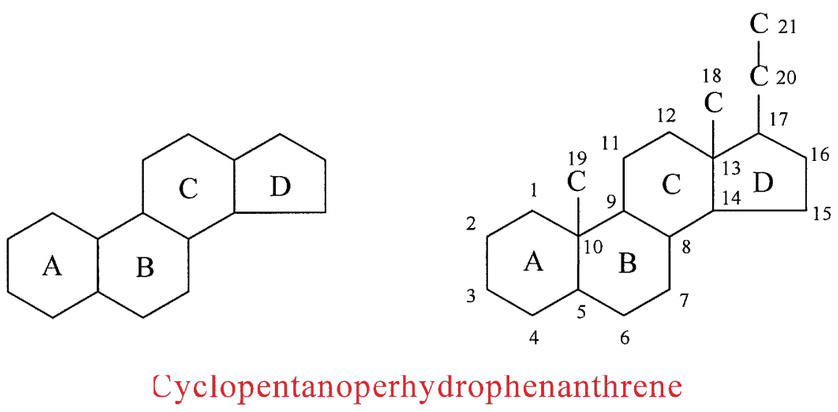

Figure 41-1 Common features and numbering system of steroids.

(e.g., cholesterol), (2) bile acids (e.g., cholanic acid), (3) sex hormones (e.g., estrogens and androgens), (4) vitamin D (sterols), and (4) corticosteroids. Steroid hormones contain up to 21 carbon atoms (C21 steroids), numbered as shown in Figure 41-1.

Steroids are three-dimensional molecules. Their constituent atoms lie in different planes, which results in the creation of isomers. The direction of the (1) hydrogen atoms, (2) substituents, and (3) side chains play a much more important role in the differentiation among various steroid compound isomers than do the relative positions of the carbon atoms in the rings. Thus, the isomers resulting from fusion of two rings are identified on the basis of the spatial relationship between the hydrogen atoms or the substituents at common carbon atoms. When rings A and B are fused, two isomers are possible depending on whether the hydrogen atom at C-5 and the methyl group at C-10 are on the same or the opposite side of the plane of the rings. If the hydrogen atom points in the same direction as that of the angular methyl group at C-10, the compound is in the cis, or normal, form. However, if they are on opposite sides, the compound is in the trans, or allo, form. Depending on which side of the molecule the substituents are attached to relative to these two methyl groups, they have either an α or β orientation. For example, when the substituents are on the same side as the two methyl groups, they have a β configuration, which is indicated by a solid line (—) joining the substituents to the appropriate carbon atoms in the nucleus. Substituents on the opposite side are attached by a broken line (– –) to denote an α configuration.

Individual steroids containing the cyclopentanoperhydrophenanthrene nucleus are differentiated by the presence of double bonds between certain pairs of carbon atoms, the introduction of substituents for the hydrogen atoms, or the addition of a specific type of side chain. On the basis of such structural characteristics, the steroidal compounds are classified as derivatives of certain parent hydrocarbons such as (1) estrane for estrogens, (2) androstane for androgens, and (3) pregnane for corticosteroids and progestins. The trivial and systematic names of several important steroid hormones are listed in Table 41-2.

TABLE 41-2 Trivial and Systematic Names of Some Important Steroid Hormones

Trivial Name	Systematic Name
Aldosterone	11β-21-Dihydroxy-3,20-dioxopregn-4-en-18-al
Androstenedione	Androst-4-ene-3,11,17-trione
Androsterone	3α-Hydroxy-5α-androstan-17-one
Cortisol	11β,17,21-Trihydroxypregn-4-ene-3,20-dione
Dehydroepiandrosterone (DHEA)	3β-Hydroxyandrost-5-en-17-one
Estradiol-17β	Estra-1,3,5(10)-triene-3,17β-diol
Estriol	Estra-1,3,5(10)-triene-3,16α,17β-triol
Estrone	3-Hydroxyestra-1,3,5(10)-trien-17-one
Etiocholanolone	3α-Hydroxy-5β-androstan-17-one
Pregnanediol	5β-Pregnane-3α,20α-diol
Progesterone	Pregn-4-ene-3,20-dione
Testosterone	17β-Hydroxy-androst-4-en-3-one
Urocortisol	3α,11β,17,21-Tetrahydroxy-(tetrahydro F) 5β-pregnan-20-one

Biochemistry

Human steroid hormones are synthesized primarily from cholesterol in the adrenal glands and gonads (see Chapter 23). Typically, cholesterol is acquired from the circulation in the form of low-density lipoprotein (LDL) cholesterol. The uptake of LDL takes place by way of specific cell-surface LDL receptors on the adrenal gland surface that internalize the cholesterol moiety, releasing it as substrate for **steroidogenesis**. Also, all steroidogenic cells are capable of de novo synthesis from acetyl coenzyme A. To ensure a continuous supply of free cholesterol for steroid synthesis, lipoprotein cholesterol uptake is coordinated with intracellular cholesterol synthesis and with the mobilization of intracellular cholesteryl ester pools. When the rate of cholesterol uptake exceeds the rate of steroidogenesis, intracellular cholesterol synthesis is suppressed, and cholesterol in excess of cellular needs is esterified and stored for future use.

The initial rate-limiting step in the transport of intracellular cholesterol to sites of steroidogenesis is mediated by a **steroidogenic acute regulatory protein (StAR)** that is regulated by **adrenocorticotropic hormone (ACTH)** from the pituitary gland.

The nature and quantity of steroid hormones produced by the adrenal glands and gonads are different. For example, the enzymes 11β-hydroxylase and 21-hydroxylase, present only in the adrenal glands, synthesize steroids characteristic of the adrenal glands. Similarly the ovaries and the testes contain enzymes that synthesize the male and female sex hormones (see Chapter 43). Enzymes participating in the biosynthesis of steroid hormones are broadly classified as (1) hydroxylases, (2) lyases, (3) dehydrogenases, and (4) isomerases.

Metabolism

The liver is the major site of steroid metabolism. In addition, the kidney and the gastrointestinal tract both carry out important

metabolic transformation of steroids. Important biochemical steps for neutralizing the potent biological activity of hormones and facilitating their rapid elimination from the systemic circulation include (1) the introduction of an additional hydroxyl group (e.g., estradiol to estriol); (2) dehydrogenation (e.g., testosterone to **androstenedione**); (3) reduction of a double bond (e.g., **cortisol** to dihydrocortisol); and (4) conjugation of an essential hydroxyl group or groups with a chemical moiety, such as glucuronic acid (e.g., testosterone to testosterone glucuronide). T e conjugation of these hormones and their metabolites with sulfuric or glucuronic acid is the most efficient single metabolic process for their excretion in the urine. Almost all steroid metabolites are excreted as water-soluble glucuronides or sulfates.

Adrenocortical Steroids

T e human adrenal cortex secretes a number of steroid hormones that are involved with a wide range of metabolic processes.

Classif cation

Steroid hormones that are classified as adrenocortical steroids include the corticosteroids and adrenal androgens. T e corticosteroids include the mineralocorticoids and glucocorticoids. T ese steroids are physiologically and quantitatively the most important group of adrenal steroids. T e structural formulas of some of the most significant biologically active corticosteroids are shown in Figure 41-2; their trivial and systematic names are listed in Table 41-2.

Mineralocorticoids (Aldosterone)

Mineralocorticoids regulate salt homeostasis (sodium conservation and potassium loss) and extracellular fluid volume. **Aldosterone** is the most potent naturally occurring mineralocorticoid and is synthesized exclusively in the zona glomerulosa region of the adrenal cortex (Figure 41-3). T is zone uniquely contains the enzyme aldosterone synthase, an obligatory enzyme in the synthetic pathway to aldosterone. It is secreted at the rate of approximately 200 µg/day.[14,15] T e actions of mineralocorticoids are summarized in Table 41-3.

Mineralocorticoids bind to a cytoplasmic mineralocorticoid receptor (MR) in the (1) distal convoluted tubule (DCT) and collecting duct of the nephron, (2) colon, and (3) salivary glands to promote sodium reabsorption and potassium and hydrogen ion excretion.[20] When a mineralocorticoid binds to the MR, the complex relocates to the nucleus, where it influences cellular DNA regulating gene transcription through the transcription factor-action of the glucocorticoid-MR complex.

Other adrenocortical steroids that have mineralocorticoid properties with varying degrees of potency include (1) deoxycorticosterone (DOC), (2) 18-hydroxy-DOC, (3) corticosterone, and (4) cortisol. A large number of analogues with mineralocorticoid and glucocorticoid activity have been synthesized; some are more potent than those that occur naturally.

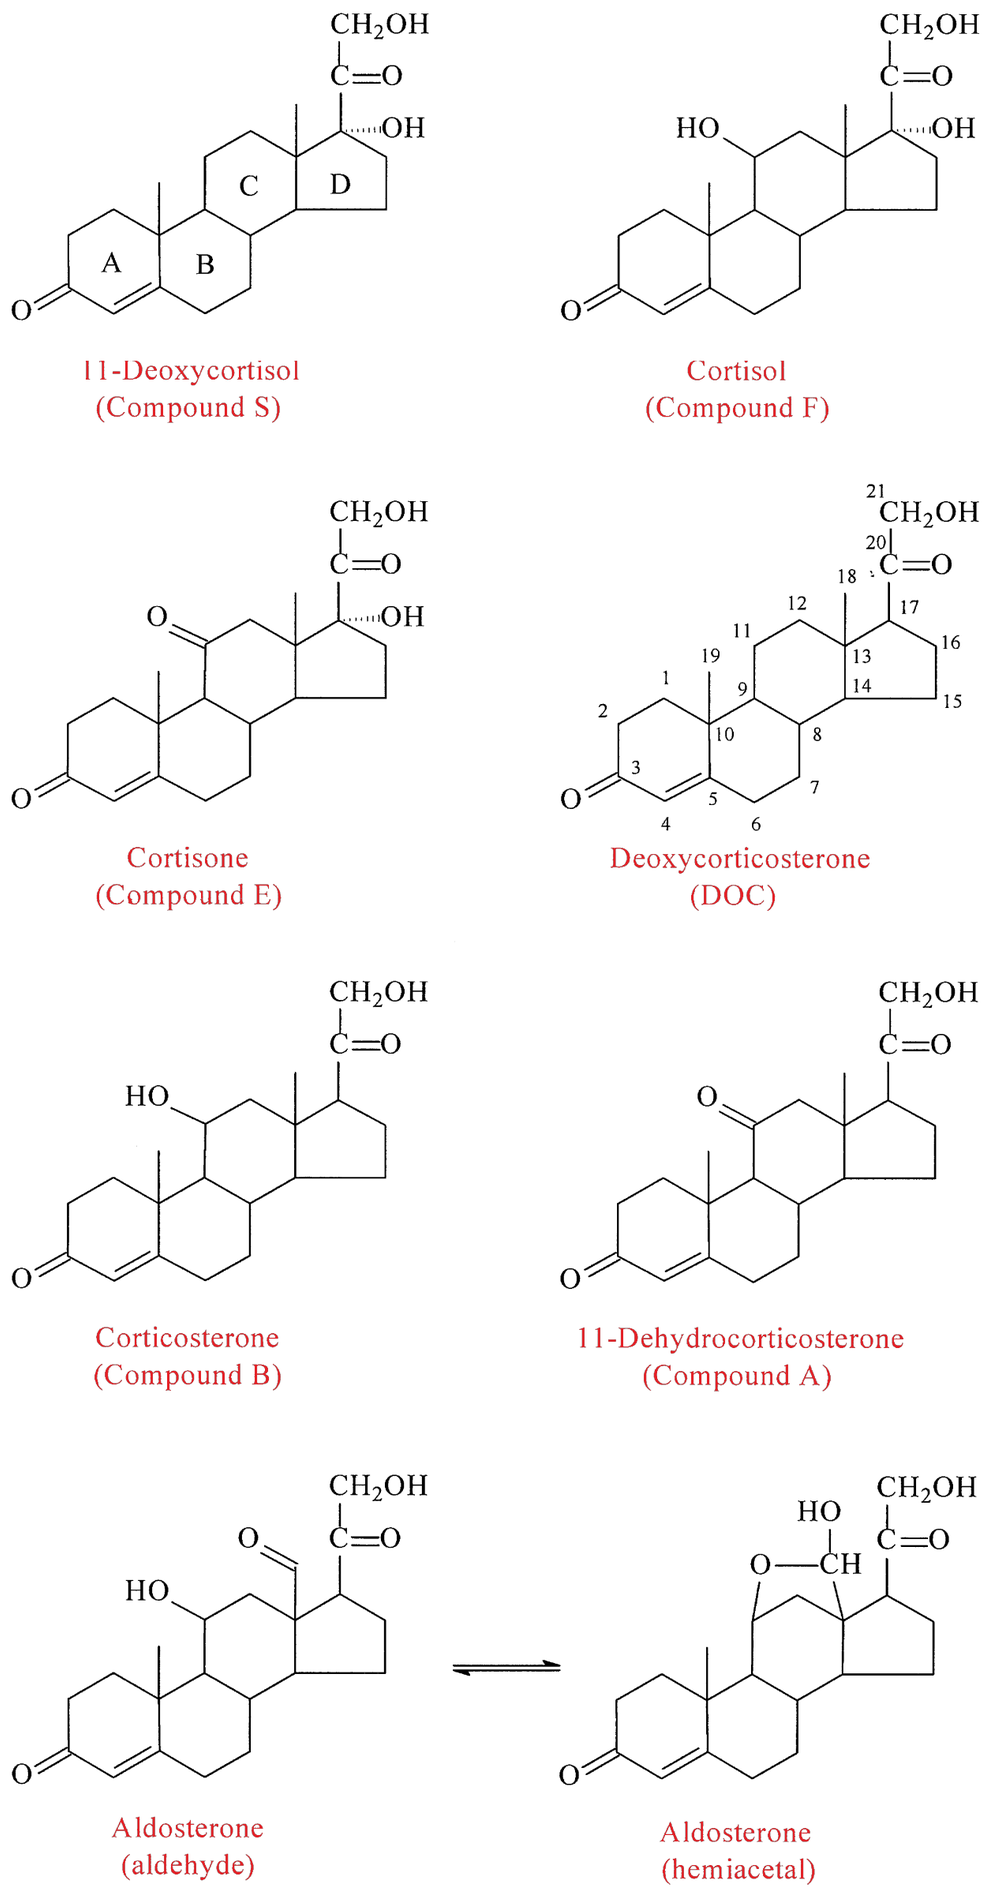

Figure 41-2 Structural formulas and trivial names of some biologically active corticosteroids. Note alphabetical ring system and the numerical system for 21 carbon atoms.

Glucocorticoids (Cortisol)

Cortisol is the major glucocorticoid synthesized from cholesterol in the zona fasciculata and reticularis of the human adrenal cortex (see Figure 41-3). It is secreted at the rate of approximately 25 mg/day. When released into the circulation, cortisol is principally bound to corticosteroid-binding globulin (CBG) and transported as such. Cortisol is metabolized and conjugated in the liver to several inactive metabolites. More than 95% of cortisol and its metabolite cortisone is conjugated to glucuronic acid and excreted into the urine as a conjugate. Less than 2% of cortisol is excreted in the urine unmetabolized as urinary free cortisol (UFC).

Glucocorticoids bind to the glucocorticoid receptor (GR) expressed in many tissues, including (1) lymphocytes, (2) hepatocytes, and (3) bone.[4] Because of the wide distribution of

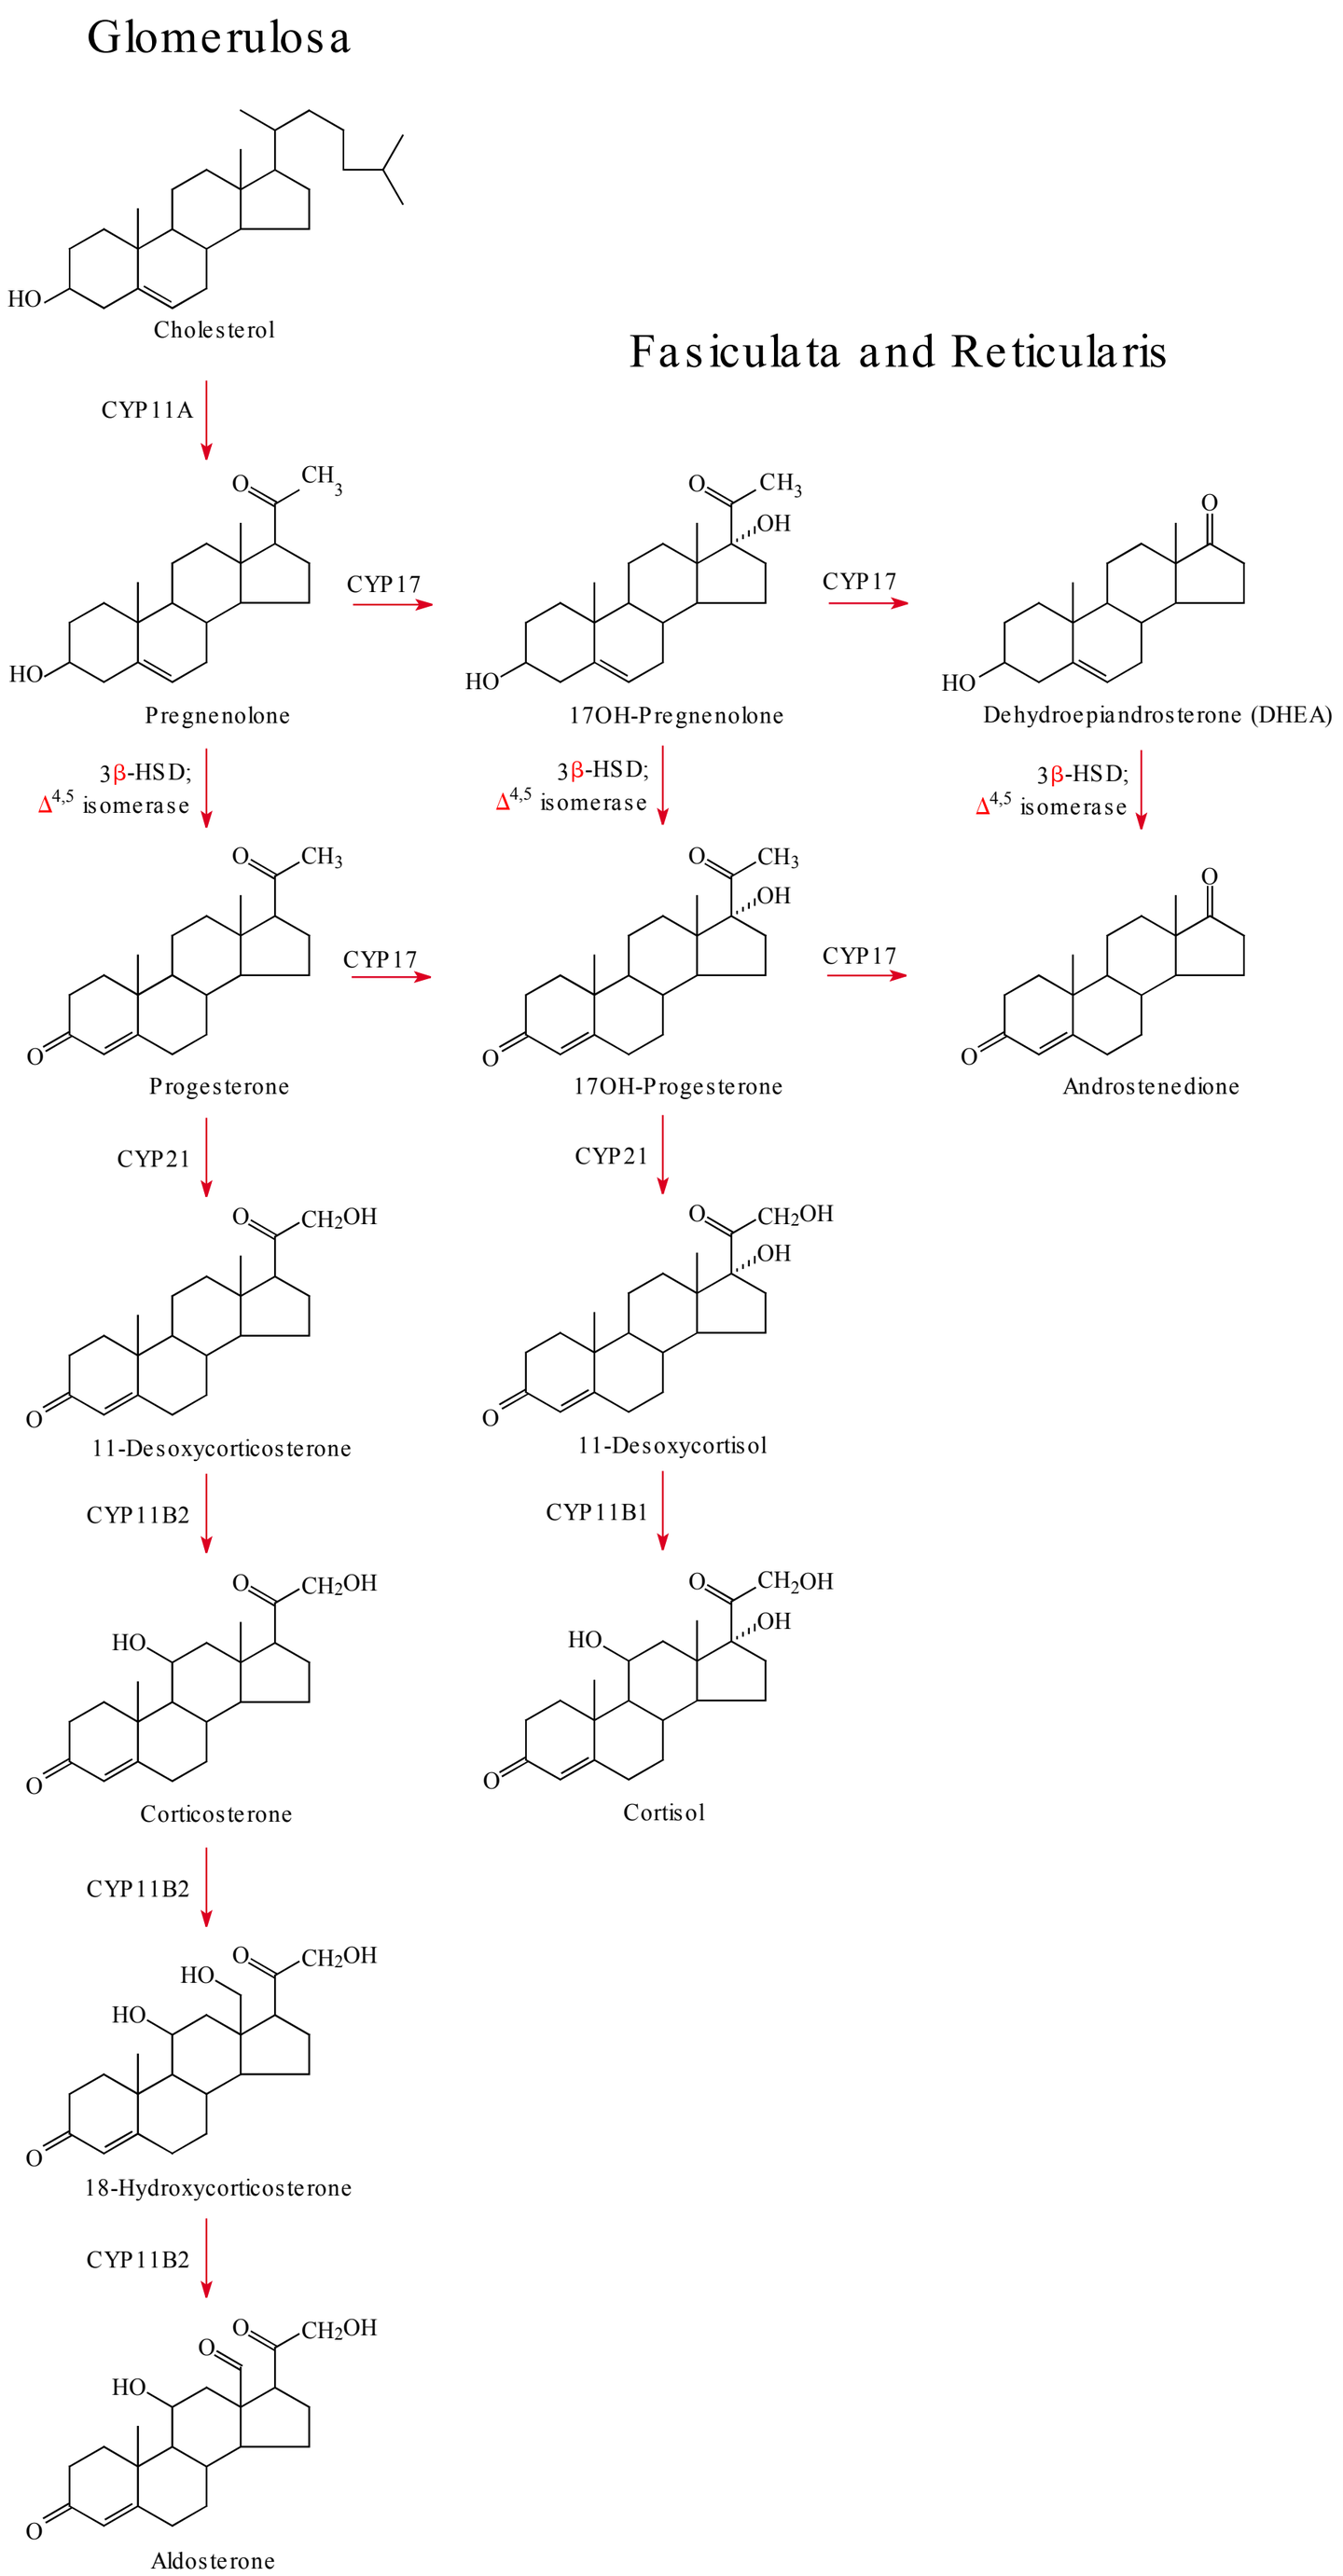

Figure 41-3 The zona glomerulosa is the site of aldosterone synthesis. CYP11B2 is under the predominant control of angiotensin II, which controls aldosterone synthesis and secretion. In the fasciculata and reticularis layers, cortisol and the adrenal androgens dehydroepiandrosterone (DHEA) and androstenedione are produced. CYP11A, 3 beta-HSD, CYP17, CYP21, and CYP11B1 are controlled by adrenocorticotropic hormone (ACTH).

TABLE 41-3 Physiological Effects of Mineralocorticoids

Action	Physiological Effect of Excessive Action	Physiological Effect of Deficient Action
Sodium retention*	Hypertension	Hypotension
Urinary potassium wasting	Hypokalemia	Hyperkalemia
Urinary hydrogen ion wasting	Alkalosis	Acidemia does not usually occur

*With consequent H_2O retention.

the GR, glucocorticoid effects are diverse, including changes in intermediary metabolism and immunoregulation.

Glucocorticoids have multiple effects on metabolism of glucose and carbohydrates, including (1) increased synthesis of gluconeogenic enzymes such as glucose-6-phosphatase and phosphoenol pyruvate carboxykinase that increase blood glucose, (2) increased liver glycogen content through activation of glycogen synthase, and (3) inhibition of glycogen phosphorylase, producing insulin resistance, in both muscle and adipose tissue, which further increases blood glucose concentrations.

Cortisol increases protein catabolism in multiple tissues. For example, excess cortisol produces (1) myopathy and consequent weakness, (2) thinning of the skin, (3) loss of strength in connective tissues, and (4) bone loss, which leads to fractures and compressed vertebrae.

Glucocorticoids have several effects on lipid metabolism including (1) adipose tissue redistribution centrally to the trunk, neck, and face, (2) increased adipocyte differentiation, (3) promotion of lipogenesis in these tissues, (4) increased very low-density lipoprotein (VLDL) and triglyceride concentrations, (5) decreased high-density lipoprotein (HDL) and HDL-cholesterol concentrations, and (6) increased activity of adipose tissue hormone-sensitive lipase, allowing triglyceride breakdown to free fatty acids and increased free fatty acid delivery to the liver. This provides substrate for hepatic triglyceride resynthesis and VLDL production and export. In addition, glucocorticoids increase appetite, which results in an increase in caloric intake and subsequent weight gain.

Glucocorticoids are powerful antiinflammatory hormones that suppress (1) the activity of pro-inflammatory enzymes (such as, cyclo-oxygenase 2 [COX-2]) and inducible nitric oxide synthase (iNOS), (2) various interleukins (IL-1, IL-2, and IL-6), (3) tumor necrosis factor-alpha, (4) interferon-gamma, and (5) E-selectin. (ACTH secretion is stimulated by IL-1, IL-6, and tumor necrosis factor-alpha.)

At physiological concentrations, glucocorticoids (1) help maintain vascular tone and cardiac output, (2) stabilize lysosomal membranes, and (3) suppress hypersensitivity responses by inhibiting the production of histamine by basophils and mast cells. Modest doses of glucocorticoids may improve one's mood, yet in pharmacologic concentrations, they may produce psychosis. The actions of glucocorticoids are summarized in Table 41-4.

TABLE 41-4 Major Targets of Glucocorticoid Action and Adverse Consequences of Excesses and Deficiencies

	ADVERSE OUTCOME	
Target Tissue	Excessive Action	Deficient Action
Central Nervous System	Polyphagia Depression or psychosis	Anorexia Depression
Endocrine System		
Carbohydrate metabolism	Hyperglycemia	Hypoglycemia
Glycogen synthesis, gluconeogenesis, insulin resistance	Increased	Decreased
Free fatty acids, triglycerides	Increased	NSE
Body weight	Increased	Decreased
Fat distribution	Centripital	NSE
Pituitary	Decreased TSH	NSE
Musculoskeletal and Connective Tissue		
Muscle	Atrophy (catabolism)	NSE
Skin	Thinning (catabolism)	NSE
Bone	Osteoporosis	NSE
Immune System	Immunosuppression	NSE

NSE, No specific effect.

Adrenal Androgens (Dehydroepiandrosterone and Androstenedione)

The adrenal androgens (1) **dehydroepiandrosterone (DHEA)**, (2) dehydroepiandrosterone sulfate (DHEA-S), and (3) androstenedione provide androgenic effects through their peripheral conversion to testosterone, which in turn binds to the androgen receptor (AR). Between ages 7 and 8, the urinary excretion of 17-ketosteroids (the breakdown products of adrenal androgens) increases as an early sign that puberty will begin in the coming 3 to 5 years.

In males, DHEA and androstenedione are not usually important because gonadal testosterone is a much more potent androgen. However, they are important in pubertal and adult women, because they produce axillary and pubic hair. Females with Turner syndrome (45,X, or "gonadal syndrome") illustrate the effects of adrenal androgens in women. Because of streak gonads (hypoplastic and dysfunctioning gonads mainly composed of fibrous tissue), adolescent girls with Turner syndrome do not experience ovarian gonadarchy (the period during which the ovaries begin to secrete estrogenic sex hormones), because essentially all of their ovarian follicles are atretic before birth. Estrogen deficiency during adolescence is manifested in (1) lack of breast development, (2) primary amenorrhea, and (3) failure of fat redistribution to the hips and buttocks. However, because adrenarchy (the increase in activity of the adrenal glands preceding puberty) is normal in adolescents with Turner syndrome, these girls will develop axillary and pubic hair despite their lack of estrogenization.

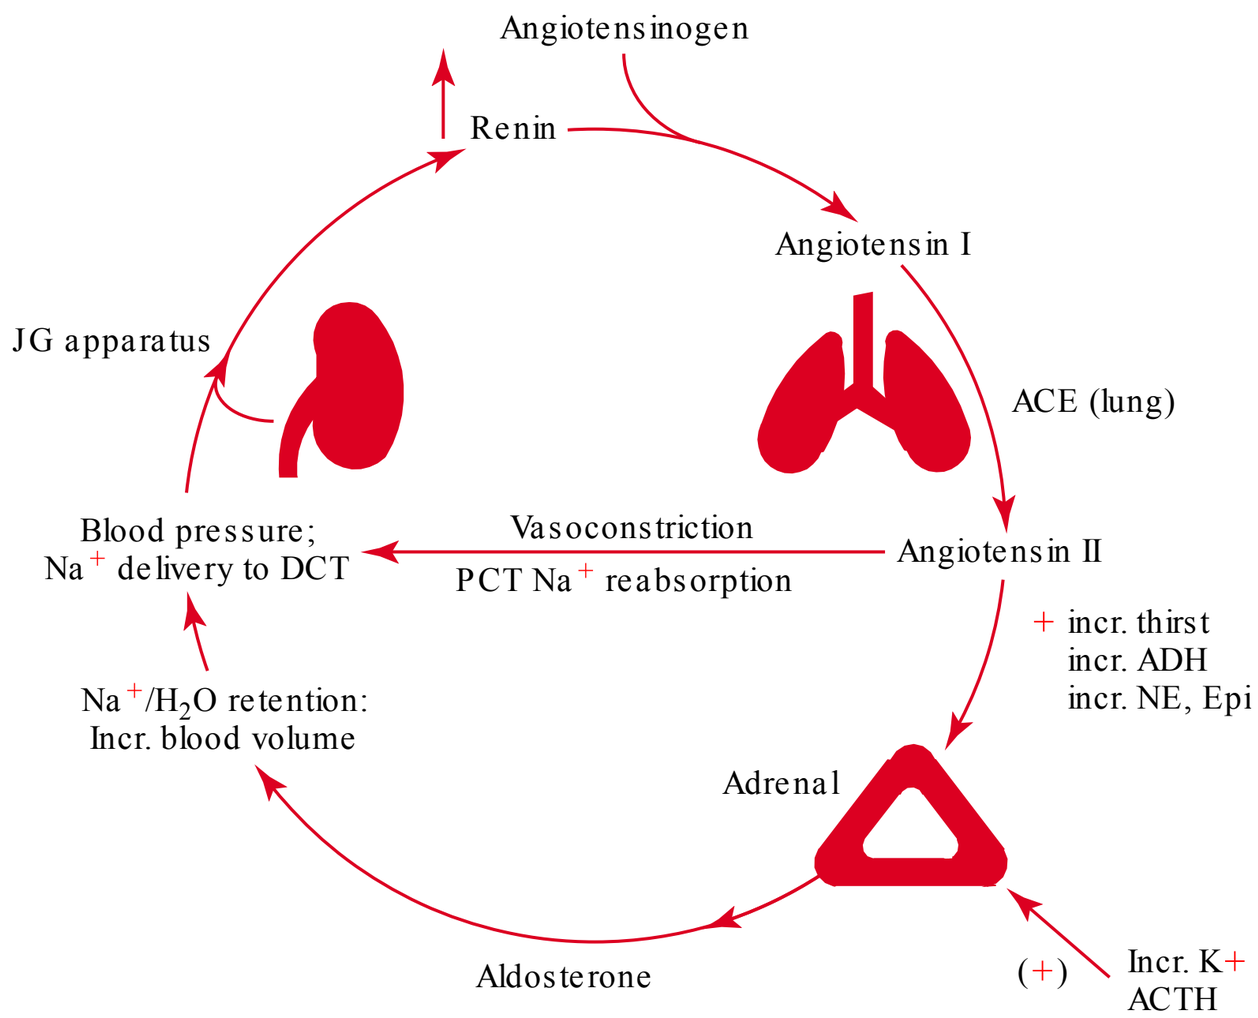

Figure 41-4 The juxtaglomerular apparatus (JGA) monitors the perfusion pressure of the glomerulus and the sodium concentration in the distal convoluted tubule (DCT). Renin is released in cases of decreased renal perfusion or decreased sodium concentration in the DCT. Renin cleaves angiotensinogen to angiotensin I. Angiotensin-converting enzyme (ACE) converts angiotensin I to angiotensin II predominantly in the lung. Angiotensin II has direct vasoconstrictive effects and stimulates sodium reabsorption by the proximal convoluted tubule (PCT); it also stimulates thirst, antidiuretic hormone (ADH) release, catecholamine release (Epi, epinephrine; NE, norepinephrine), and aldosterone synthesis and secretion. Aldosterone increases sodium reabsorption, and, as water follows salt, blood volume increases along with blood pressure. Overall these effects act to restore renal perfusion. Adrenocorticotropic hormone (ACTH) and increased potassium have minor effects in stimulating aldosterone synthesis and secretion.

Regulation of Adrenocortical Hormones

Steroid hormones are not stored in hormone-producing cells and therefore must be produced as needed. Steroids are lipophilic and therefore (1) pass through cell membranes to exit the hormone-producing cells, (2) enter the circulation to be distributed throughout the body, and (3) enter the cytoplasm of target cells where they bind to nuclear receptors. Translocation of the hormone-receptor complex to the nucleus initiates the action of the hormone. Growing evidence suggests that steroid hormones may also act independently of their effect on DNA transcription. In the case of glucocorticoids, there is evidence that the GR may be expressed on the cell surface, explaining some of the immediate effects of glucocorticoids on cellular physiology.

Aldosterone

The production and secretion of aldosterone are regulated by the renin-angiotensin system. As shown in Figure 41-4, **renin** is an enzyme that cleaves the leucine-leucine bond in **angiotensinogen** (a serum α_2-globulin secreted in the liver) to generate angiotensin I. Angiotensin I is the precursor of **angiotensin II**, a polypeptide hormone with important functions in control of arterial pressure and other physiological variables. The rate-limiting component in this system is renin release, which is regulated by the juxtaglomerular apparatus (JGA) of the kidney (see Chapter 35). The JGA is composed of modified smooth muscle cells that synthesize and secrete renin. The JGA cells function as baroreceptors, responding to increased pressure in the arteriole leading to the glomerulus. Decreased renal perfusion pressure leads to renin release. This is the most important mechanism regulating renin concentrations in the circulation.

The macula densa consists of specialized cells that line the DCT. Compared with other tubular cells, these cells are unique in that their nuclei are near the apical (luminal) pole of the cell, whereas the Golgi apparatus is near the basolateral pole of the cell. Acting as a chemoreceptor, the macula densa monitors the sodium concentration in the DCT. If the sodium concentration declines, the macula densa signals the JGA cells, via prostacyclin, to release renin. Anatomically, the DCT passes between the afferent and efferent arterioles of the nephron, which, respectively, supply blood to, and drain blood from, the glomerular capillaries.

Decreased sodium delivery to the DCT results from hyponatremia or decreased glomerular filtration, both of which elicit renin release. Norepinephrine and dopamine stimulate renin release via sympathetic innervation of the β-adrenoreceptors located in the JCA. Thus, with upright posture and catecholamine release, renin release is enhanced. Potassium also directly stimulates renin release.

Overall, renin is physiologically released in response to (1) **hypovolemia**, (2) reduced cardiac output, (3) systemic vasodilation, (4) selectively reduced renal perfusion, (5) hyponatremia, and (6) stress (mediated by catecholamines).

Angiotensinogen is an α_2-globulin synthesized in hepatocytes. Renin cleaves angiotensinogen to form the decapeptide angiotensin I. Angiotensin I has no (1) endocrine, (2) paracrine, or (3) autocrine effects. **Angiotensin-converting enzyme** (ACE), a zinc metallopeptidase that occurs mostly in the lung, removes the two C-terminal residues from angiotensin I to generate the octapeptide angiotensin II, the most active form of the hormone. Further degradation of angiotensin II by aminopeptidase A yields the heptapeptide angiotensin III. T e ratio of angiotensin II to angiotensin III is usually 4 to 1.

Angiotensin II acts to preserve circulating blood volume and maintain blood pressure through several mechanisms: (1) stimulation of aldosterone synthase (CYP11B2) to produce aldosterone; (2) direct vasoconstriction; (3) increased release of epinephrine and norepinephrine from the adrenal medulla, which will also act as vasoconstrictors; (4) stimulation of sodium reabsorption in the proximal convoluted tubule (PCT); (5) stimulation of thirst; and (6) stimulated release of antidiuretic hormone (ADH). Angiotensin III has equivalent potency in stimulating aldosterone secretion.

Cortisol

Cortisol release is controlled through a hypothalamic-pituitary-end organ negative feedback system (Figure 41-5). With this system, corticotropin-releasing hormone (CRH) secretion is stimulated by (1) stress, (2) exercise, and (3) hypoglycemia. Stress may be physiological, including (1) pain, (2) trauma, (3) surgery, and (4) hemorrhage, or psychological, due to severe anxiety and/or depression. Prolonged administration of large doses of glucocorticoids will suppress the hypothalamic-pituitary-adrenal axis, leading to adrenal atrophy. T erefore, abrupt termination of exogenous steroids may induce acute and possibly life-threatening glucocorticoid insufficiency.

CRH is secreted by cells in the paraventricular nucleus of the hypothalamus, and reaches the anterior pituitary gland through the hypothalamic pituitary portal system. Corticotrophs represent about 20% of functional anterior pituitary cells and express receptors for CRH that promote synthesis, storage, and release of adrenocorticotropin (ACTH). ACTH release from the pituitary is also stimulated by ADH, but to a lesser degree than by CRH. T e pro-inflammatory cytokines (1) IL-1, (2) IL-6, and (3) tumor necrosis factor-alpha also stimulate ACTH release.

Circulating ACTH binds to receptors located on cells within the adrenal cortex, triggering activity by protein kinase A and protein kinase C, leading to (1) steroidogenesis, (2) increased size and number of adrenocortical cells, and (3) increased size and functional complexity of cellular organelles, all of which result in synthesis and release of cortisol. Cortisol feedback occurs centrally at the hypothalamus, and to a lesser degree at the anterior pituitary, to suppress

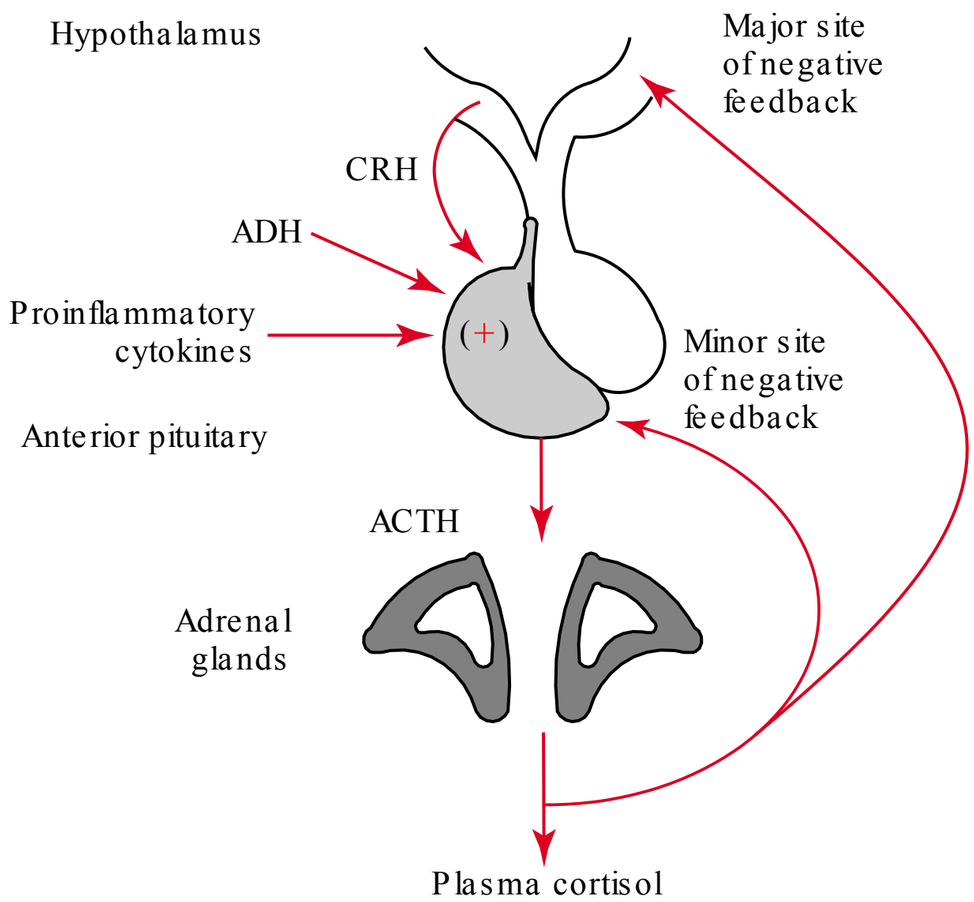

Figure 41-5 Cortisol is controlled through a traditional hypothalamic-pituitary-end organ negative feedback system. Corticotropin-releasing hormone (CRH) is released from the hypothalamus and is delivered to the anterior pituitary via the hypothalamic-pituitary portal system. CRH releases adrenocorticotropic hormone (ACTH) from anterior pituitary corticotroph cells. Increased concentrations of antidiuretic hormone (ADH) and proinflammatory cytokines (such as IL-1, IL-6, and tumor necrosis factor-alpha) can also stimulate ACTH release. ACTH stimulates the synthesis and release of cortisol from the adrenal cortex. Cortisol feeds back negatively at the pituitary, but the major site of negative feedback is the hypothalamus.

CRH and ACTH secretion, respectively. Other negative feedback loops include (1) ACTH suppression of hypothalamic CRH and (2) an ultra-short feedback loop whereby ACTH suppresses its own release.

Pulses of CRH cause the release of ACTH, which stimulates cortisol secretion. T ere is wide diurnal variation in the secretion of cortisol with highest concentrations in the early morning (about 2 hours before awakening) and lowest concentrations near midnight (assuming that the individual sleeps overnight).

Adrenal Androgens

T e regulation of adrenal androgen synthesis and secretion is not well understood.[12] T e best characterized regulator of androstenedione and DHEA secretion, however, is ACTH. A diurnal rhythm in adrenal androgen concentrations parallels cortisol variations. Nevertheless, ACTH regulation of adrenal androgens does not explain the normal prepubertal and pubertal increases in adrenal androgen synthesis that occur in both boys and girls because ACTH does not increase prior to puberty.

Circulation

Circulating adrenocortical steroid hormones are 90% to 98% bound to specific carrier proteins or albumin. Unbound steroids in the plasma are mostly conjugated to sulfate or glucuronic acid. Aldosterone is carried primarily by albumin since

(1) cortisol, (2) corticosterone, and (3) 17-hydroxyprogesterone occupy most of the binding sites on CBG. Typical concentrations of cortisol exceed those of aldosterone by many-fold, explaining why little aldosterone is carried on CBG.

Between 80% and 90% of cortisol is carried by CBG, 7% of cortisol is loosely bound to albumin, and 2% to 3% is unbound (free). When total cortisol is increased, the increased plasma free cortisol readily spills into the urine, increasing the UFC excretion. Typically, only 0.25% to 0.5% of total cortisol is excreted in the urine. Because more cortisol than aldosterone is bound to CBG (which slows clearance), the half-life of cortisol is longer (60 to 80 minutes) than the half-life of aldosterone (20 to 30 minutes). In pregnancy, CBG may increase two- to threefold in response to estrogens. Some patients with chronic active hepatitis may display increased concentrations of CBG. Conversely, CBG concentrations are decreased in (1) nephrosis (as a result of CBG loss in the urine), (2) cirrhosis (because of decreased production), (3) hyperthyroidism (due to increased metabolism), and (4) with glucocorticoid treatment (probably as a result of enhanced protein catabolism). Even with changes in total cortisol due to changes in CBG, the concentration of free cortisol remains stable if the hypothalamic-pituitary-adrenal axis is functioning normally.

DHEA and its sulfated form, DHEA-S, and estradiol are predominantly bound to albumin, whereas testosterone and dihydrotestosterone (DHT) are mostly bound to sex hormone–binding globulin (SHBG). Estrogens and thyroid hormone increase SHBG concentrations, whereas (1) insulin, (2) growth hormone, (3) glucocorticoids, (4) androgens, and (5) progestins lower SHBG concentrations. SHBG concentrations are higher in children than in adults.

Metabolism

The liver is the major site of steroid metabolism (Figure 41-6), via P450 enzymes with the kidney playing less of a metabolic role but an important excretory role. Clearance of steroid hormones involves (1) hydroxylation, (2) dehydrogenation, (3) reduction of double bonds, and (4) conjugation to sulfates or glucuronides. The reduction in steroid concentrations increases their solubility and provides functional sites (such as, hydroxyl groups) for their conjugation to sulfate or glucuronic acid; this increases their solubility in urine, promoting their excretion. Approximately 90% of conjugated steroids are excreted by the kidney.

Cortisol metabolism and clearance affect cortisol concentrations. If the clearance of cortisol is reduced, plasma cortisol concentrations increase, whereas enhanced clearance of cortisol decreases its concentrations.

Urinary Metabolites

Measurement of the urinary excretion of adrenocortical hormones may be useful in the laboratory assessment of adrenal disease. However the difficulty of accurately collecting timed urine samples remains a challenge, and serum or plasma steroid assays are often preferred. Immunoassays for the major circulating steroid hormones are widely available.

Biochemically 17-hydroxyprogesterone is reduced to pregnanetriol, which typically is measured in urine. Before the development of immunoassays for 17-hydroxyprogesterone, a 24-hour urine was collected for measurement of pregnanetriol excretion in most types of **congenital adrenal hyperplasia (CAH)**. The urinary metabolites of 11-desoxycortisol and cortisol are classified as 17-hydroxycorticosteroids (17-OHCS). Analytically, 17-OHCS are photometrically measured by the reaction of 17,21-dihydroxy-20-oxosteroids with a phenylhydrazine-ethanol-sulfuric acid reagent, producing yellow phenylhydrazones called the Porter-Silber chromogens.

Collectively, the urinary metabolites are (1) 17-hydroxyprogesterone, (2) 11-desoxycortisol, and (3) cortisol are 17-ketogenic steroids (17-KGS). Ketogenic steroids have been measured using the Zimmermann reaction, in which an alkaline solution of meta-dinitrobenzene reacts with methylene groups at carbon-16 of the 17-ketosteroids.

Dynamic Tests of Adrenal Function

Several tests are used to assess adrenal function. These tests are typically designed to differentiate between primary and secondary causes of disease, or to detect abnormalities that may not be apparent in the results of static, baseline laboratory measurements. A stimulus is applied, and the release of a given hormone over a specific time frame is measured. Alternatively, suppression tests are used to determine whether physiological feedback mechanisms are intact.

Adrenocorticotropic Hormone Stimulation (Cosyntropin) Tests

ACTH stimulation tests are designed to document the functional capacity of the adrenal glands to synthesize cortisol. In the test, the adrenal glands are stimulated by cosyntropin (also called tetracosactrin; Synacthen and Cortrosyn are brand names), a synthetic polypeptide that is the N-terminal 24 amino acid sequence of ACTH and contains the biologically active domain of the hormone. It is a potent stimulator of cortisol secretion, and it has a very short half-life and minimal antigenicity. The test determines whether the adrenal glands are responsive to ACTH.

Corticotropin-Releasing Hormone Stimulation Test

A direct and selective test of anterior pituitary gland function is the CRH stimulation test. Injection of ovine CRH stimulates ACTH secretion in healthy subjects within 60 to 180 minutes; glucocorticoids inhibit this effect (as in cases of **Cushing syndrome** resulting from an adrenal adenoma or ectopic ACTH secretion by a tumor).

Insulin-Induced Hypoglycemia Stimulation Test

To test the integrity of the hypothalamic-pituitary-adrenal axis, indirect tests of ACTH secretion rely on the adrenal response to signals that stimulate ACTH release. In the insulin-induced hypoglycemia stimulation test, insulin is given to produce hypoglycemia which is a physiologic stimulus for release of CRH; plasma ACTH or cortisol concentrations are then measured and will be increased if the hypothalamic-pituitary-adrenal

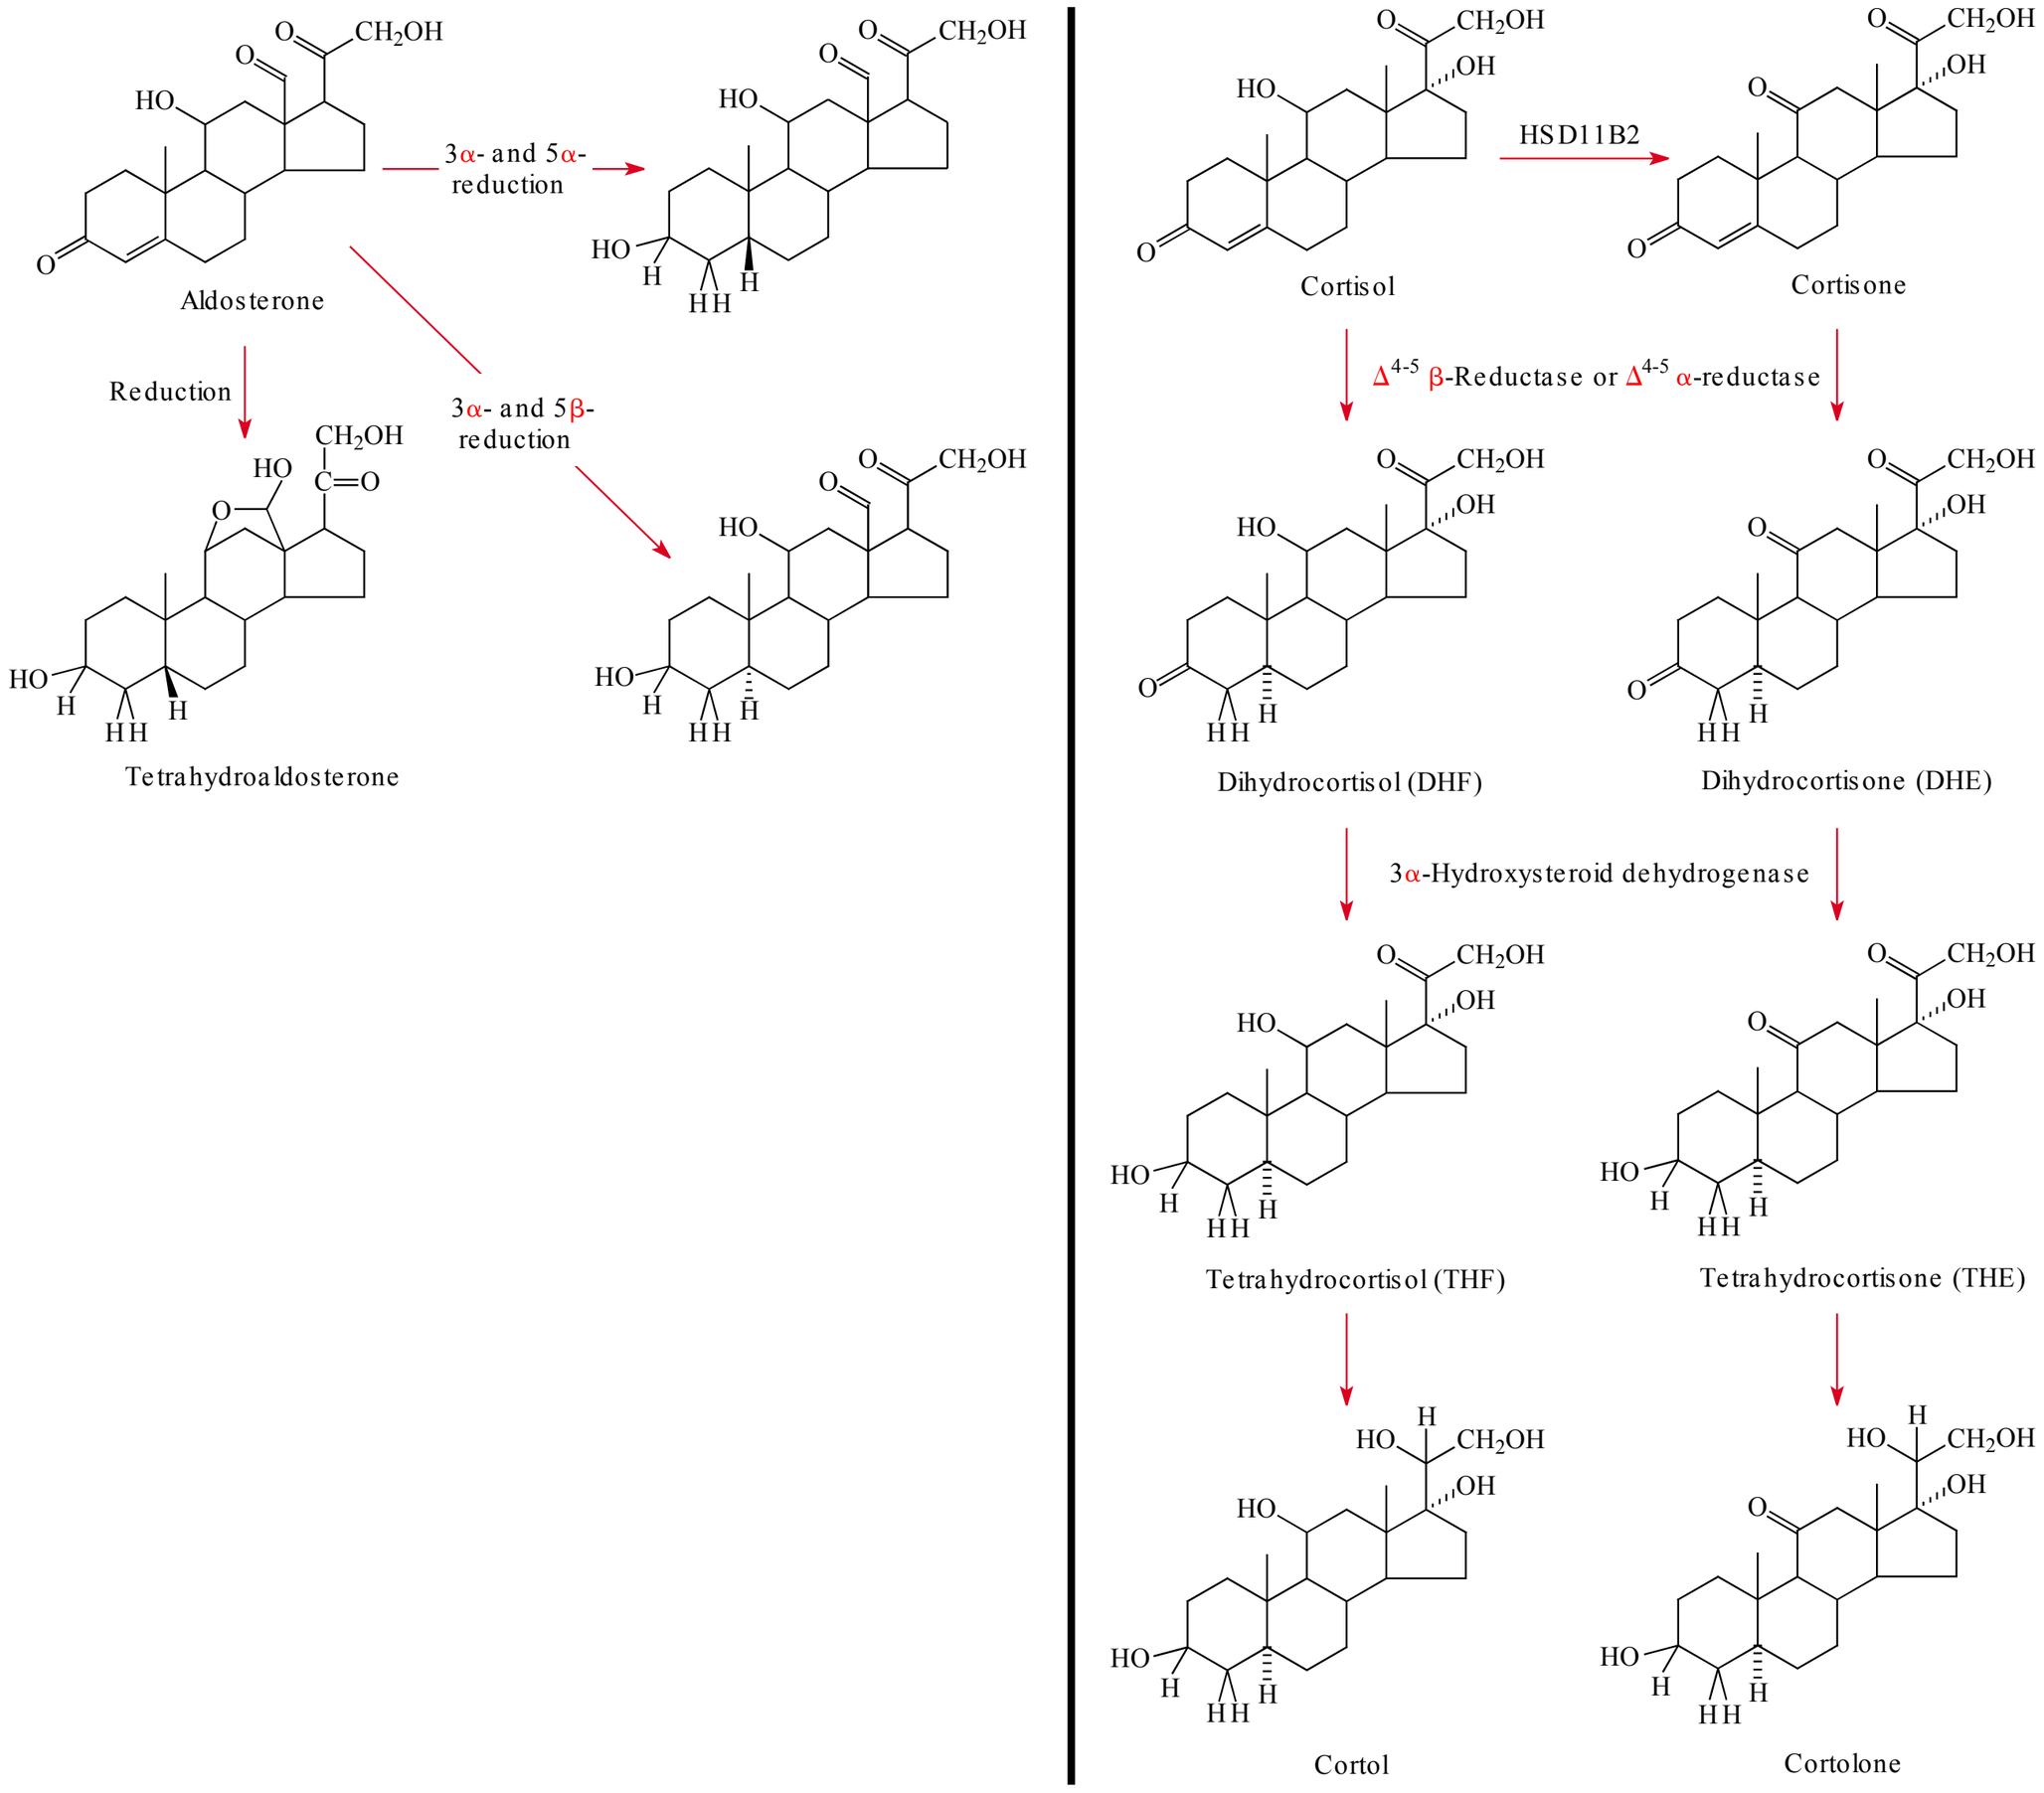

Figure 41-6 Left panel: Aldosterone metabolism: Aldosterone is reduced to tetrahydroaldosterone. Aldosterone is 3 alpha- and 5 alpha-reduced, or 3 alpha- and 5 beta-reduced. Right panel: Cortisol metabolism: Cortisone is formed from cortisol via 11-beta hydroxysteroid dehydrogenase-2 (HSD11B2). Reduction of the double bonds at carbons 4-5 via delta(4)-5 beta reductase or delta(4)-5 alpha reductase yields dihydrocortisol (DHF) and dihydrocortisone (DHE). Metabolism with reduction of the ketone groups at carbon 3 results in tetrahydrocortisol (THF) and tetrahydrocortisone (THE), which account for the major portion of cortisol clearance (≈50%). Further metabolism of THF and THE via 20-alpha hydroxysteroid dehydrogenase or 20-beta hydroxysteroid dehydrogenase produces alpha and beta cortol and cortolone (the cortoic acids), which account for ≈30% of cortisol excretion.

axis is intact. T is test involves risks of hypoglycemia such as (1) obtundation/decreased mental capacity, (2) seizure, (3) coma, and (4) death; it should be performed only under carefully supervised conditions. Venous access must be maintained during the procedure to facilitate rapid administration of glucose should hypoglycemia not spontaneously resolve or a hypoglycemia-induced seizure occur requiring immediate administration of intravenous glucose.

Metyrapone Stimulation Test

A less risky indirect test of hypothalamic-pituitary-adrenal axis function involves the administration of metyrapone, an inhibitor of the 11 β-hydroxylase enzyme (CYP11B1) that converts 11-desoxycortisol to cortisol. T e decrease of cortisol is expected to allow an increase in ACTH secretion. Several protocols have been designed to directly or indirectly monitor the effect of metyrapone on ACTH secretion.

Dexamethasone Suppression Test

In healthy individuals, an increase in cortisol inhibits CRH release from the hypothalamus, resulting in decreased production of ACTH and, subsequently, of cortisol. With the dexamethasone suppression test, the integrity of this feedback mechanism is assessed by administering the potent glucocorticoid dexamethasone, and measuring serum or urine cortisol concentrations to evaluate the hypothalamic response. Several dexamethasone suppression tests are available for clinical use. Dexamethasone is chosen for suppression testing, because it does not significantly cross-react in cortisol immunoassays. Patients with Cushing syndrome of any cause will fail to suppress their morning plasma cortisol concentration to less than 2 μg/dL in response to a 1-mg dose of dexamethasone administered at 22:00. This is a screening test, and confirmation of Cushing syndrome requires repeat testing or measurement of urinary cortisol on at least two separate days or some other combination of tests.

Mineralocorticoid Stimulation Tests

The renin-angiotensin-aldosterone system responds to (1) blood volume, (2) blood pressure, and (3) electrolyte balance (and imbalance). Sodium excretion and extracellular fluid volume are inversely correlated with plasma renin and aldosterone concentrations. Procedures for stimulating the renin-angiotensin system are based on volume depletion maneuvers, such as (1) sodium restriction, (2) upright posture, or (3) diuretic administration.

In the furosemide stimulation test, the diuretic furosemide (40 to 80 mg) is administered to decrease plasma volume, followed by 4 hours of upright posture. This test does not require hospitalization or special diets, although it is recommended that the patient maintain a diet with a normal salt intake. The normal response is a two- to threefold increase in plasma renin, indicating that the JGA is responding properly to decreased plasma volume.

Another simple and convenient stimulation test consists of sodium restriction and upright posture. Dietary sodium is restricted to less than 20 mmol/day for 3 to 5 days; urine is collected for creatinine and sodium measurements until equilibrium with the new diet is established. Plasma renin activity (PRA) is measured after 2 hours of standing. A normal response is a two- to threefold increase in plasma renin. In a patient with mineralocorticoid deficiency, hydration status should be assessed carefully to prevent the development of acute hypovolemia and its potential adverse consequences.

Mineralocorticoid Suppression Tests

Mineralocorticoid suppression tests use either (1) saline infusion, (2) oral salt loading, or (3) mineralocorticoid administration, each of which should suppress the secretion of aldosterone by the adrenal gland. In healthy individuals, acute expansion of plasma volume with salt increases renal perfusion, suppresses renin release, and decreases aldosterone secretion. If hypertension is present, this test can potentially raise the patient's blood pressure to undesirable levels.

Disorders of the Adrenal Cortex

Thomas Addison first reported hypofunction of the adrenal cortex in 1855.[16] Subsequently, many diseases associated with abnormal adrenal function have been discovered and studied.

Although circulating concentrations of adrenal androgens decline with advancing age, it is unclear whether this simply reflects physiological changes associated with aging, or if it is a pathological condition that should be treated. Most experts believe the former and do not recommend adrenal androgens as "treatment" for aging. Adrenal androgen deficiency occurs as part of primary adrenal failure in aging, but it has no clear pathologic consequences.

Adrenal Insufficiency (Addison Disease)

Adrenal insufficiency causing combined mineralocorticoid and glucocorticoid deficiency is a rare disorder with a prevalence of only 4 to 11 cases per 100,000. If left untreated, adrenal insufficiency can be fatal. Cortisol deficiency is classified as primary, secondary, or tertiary.

Primary adrenal insufficiency, also known as **Addison disease**, results from progressive destruction or dysfunction of the adrenal glands by (1) an autoimmune process, (2) a systemic disorder, (3) an inborn error of metabolism (endogenous causes), or (4) by an exogenous cause, such as infection (Table 41-5). Worldwide, the most common cause of primary adrenal insufficiency is infectious diseases which include (1) tuberculosis, (2) fungal infections (histoplasmosis, cryptococcosis, North and South American blastomycosis, sporotrichosis, and coccidiomycosis), and (3) cytomegalovirus infection. Syphilis produces a syphilitic gumma (a fibrotic and granulomatous lesion) that destroys the adrenal gland. In patients with AIDS, opportunistic infections with (1) cytomegalovirus, (2) fungi, (3) mycobacteria, and other microbes have been known to damage the adrenal gland. Autoimmune adrenalitis accounts for more than 70% of cases reported in developed countries, with adrenal autoantibodies measurable in more than 75% of these cases. In adrenal insufficiency the adrenal glands are atrophic with loss of cortical cells but an intact medulla.

The most common inborn errors of steroidogenesis involve defects in the the synthesis of cortisol, with or without concurrent aldosterone deficiency. Because such disorders commonly lead to excessive adrenal androgen production, they are discussed in a later section concerning hyperfunction of the adrenal cortex. The onset of clinical manifestations is usually gradual, and the degree and severity of symptoms depend on the extent of adrenal failure. In early or mild expressions of primary adrenal insufficiency, hypofunction may not be evident unless the patient is under stress (e.g., following trauma or surgery). Complete glucocorticoid deficiency manifests in a variety of ways, including (1) fatigue, (2) weakness, (3) weight loss, (4) gastrointestinal disturbance, and (5) fasting hypoglycemia. Mineralocorticoid deficiency leads to dehydration with (1) hypotension, (2) acidosis, (3) hyponatremia, and (4) hyperkalemia. Excessive pituitary synthesis and release of ACTH, unchecked by the negative feedback system, may cause

TABLE 41-5 Causes of Primary Adrenal Insufficiency or Failure of Aldosterone Production

Endogenous Causes	
Autoimmune disease	Sporadic
	Autoimmune polyglandular syndrome type 1 (Addison disease, candidiasis, hypoparathyroidism, and primary gonadal failure)
	Autoimmune polyglandular syndrome type 2 (Addison disease, primary hypothyroidism, primary hypogonadism, diabetes, and pernicious anemia)
Inborn errors	Congenital adrenal hyperplasia (CAH)
	Congenital adrenal hypoplasia (DAX-1 mutation)
	Demyelinating disorders: adrenoleukodystrophies
	Childhood X-linked recessive adrenoleukodystrophy (Brown-Schilder disease)
	Neonatal autosomal recessive adrenoleukodystrophy
	X-linked recessive adrenomyeloneuropathy (sudanophilic leukodystrophy)
	Familial (isolated) glucocorticoid deficiency (degeneration of fasciculata-reticularis layers)
	Wolman disease (lysosomal acid lipase deficiency)
	Steroidogenic factor-1 (SF-1) mutations
	Mitochondrial forms of Addison disease (Kearns-Sayre syndrome)
	Smith-Lemli-Opitz syndrome (sterol delta-7-reductase mutations)
	Adrenocorticotropic hormone (ACTH) resistance syndromes
Vascular disorders	Intra-adrenal hemorrhage (Waterhouse-Friderichsen syndrome; caused by infection [especially Neisseria meningitidis, but also Pseudomonas aeruginosa, Haemophilus influenzae, Streptococcus pyogenes, or Streptococcus pneumoniae]) or anticoagulants
Glandular infiltration	Neoplastic
	Leukemia, lymphoma, carcinoma of the lung, carcinoma of the breast
	Non-neoplastic
	Amyloid
	Hemochromatosis
Exogenous Causes	
Infection	Granulomatous disease
	Tuberculosis, sarcoidosis, histoplasmosis, cryptococcosis, blastomycosis (North and South American), sporotrichosis, and coccidiomycosis
	Other infections
	Cytomegalovirus, opportunistic infections in HIV
Drugs	Blockers of steroid synthesis: mitotane, aminoglutethimide, trilostane, ketoconazole, metyrapone
	Glucocorticoid receptor blockers: Mifepristone (RU-486)
Abdominal Irradiation	
Bilateral adrenalectomy	Intra-adrenal thrombosis: renal vein thrombosis in neonates, heparin-induced thrombocytopenia, antiphospholipid syndrome
Causes of Deficient Mineralocorticoid Activity	
Failure of Aldosterone Production (Decreased Aldosterone)	
Hyperreninemic hypoaldosteronism (synthetic deficiency)	Primary adrenal insufficiency
	Selective aldosterone deficiency
	Inborn errors (e.g., CYP11B2 mutations)
	Drug-induced aldosterone suppression
	Heparin (direct inhibition of aldosterone secretion)
	Angiotensin-converting enzyme (ACE) inhibitors
	Angiotensin receptor blockers (ARBs)
	Hypoaldosteronism in critical illness/hypotension (e.g., selective zona glomerulosa injury)[2]
Hyporeninemic hypoaldosteronism (deficient aldosterone stimulation)	Renin deficiency (e.g., diabetes, renal failure)
Deficient Aldosterone Action (Resistance to Aldosterone; Increased Aldosterone)	
Pseudohypoaldosteronism, type 1	Renal
	Multiple target organ defects
	Early childhood hyperkalemia

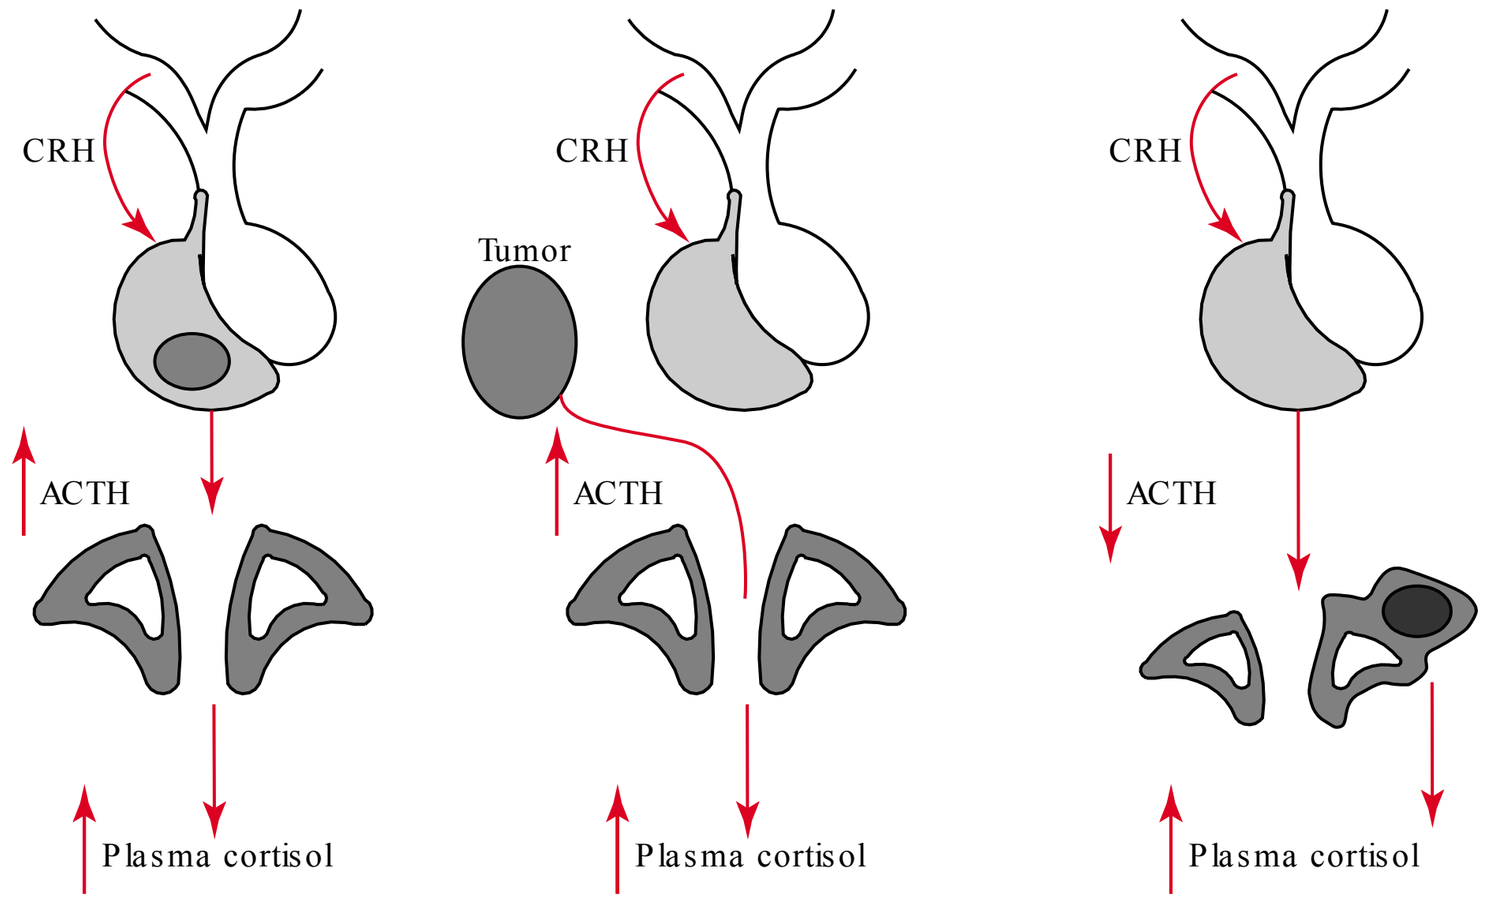

Figure 41-7 Endogenous Cushing syndrome is also classifed as Cushing disease (left panel), ectopic ACTH syndrome (middle panel), or adrenal Cushing syndrome (right panel). ACTH is elevated in cases of Cushing disease and ectopic ACTH syndrome. ACTH is suppressed in cases of adrenal Cushing syndrome.

hyperpigmentation of the skin and mucous membranes due to stimulation of melanin production.

In secondary and tertiary adrenal insufficiency, inadequate cortisol production may be due to destructive processes in the hypothalamus and/or pituitary that result in a decreased ability to secrete CRH (tertiary adrenal insufficiency) or ACTH (secondary adrenal insufficiency). However, the most common cause of tertiary cortisol insufficiency is long-term administration of glucocorticoids that suppress CRH, leading to a decrease in both ACTH release and cortisol secretion due to adrenal atrophy. Clinical features of glucocorticoid deficiency in secondary and tertiary adrenal insufficiency are similar to those of primary insufficiency, except that hyperpigmentation is not present and hypotension is less severe. Mineralocorticoid deficiency, hyperkalemia, and ACTH excess are not features of secondary or tertiary adrenal insufficiency. T e cosyntropin stimulation test, which tests how well the adrenal glands responde to ACTH, distinguishes primary adrenal insufficiency (impaired response to cosyntropin) from secondary or tertiary causes of adrenal insufficiency.

ACTH and cortisol concentrations often are not useful for establishing the diagnosis of secondary adrenal insufficiency. Episodic secretion and circadian variation result in ACTH and cortisol concentrations that overlap between normal subjects and individuals with secondary or tertiary adrenal insufficiency.[9] A morning cortisol is a useful screening test for adrenal insufficiency since concentrations are highest in the morning; morning cortisol in patients with adrenal insufficiency usually is below 10 μg/dL.

Although subnormal basal plasma concentrations of DHEA-S occur in (1) primary, (2) secondary, and (3) tertiary forms of adrenal insufficiency, DHEA-S measurements are of limited value in the diagnosis of adrenal insufficiency. Low concentrations of adrenal androgens are normally observed in young children (before ages 7 to 9) and in the elderly.

Measurement of adrenal autoantibodies may be useful in evaluating patients suspected of adrenal insufficiency.[3] Such autoantibodies are detected by indirect immunofluorescence (adrenal cytoplasmic autoantibodies [ACA]) or by ELISA (21-hydroxylase autoantibodies).

Hypoaldosteronism

Deficient aldosterone production also occurs in conditions other than Addison disease. For example, isolated aldosterone deficiency accompanied by normal cortisol production occurs in patients with (1) inadequate production of renin by the kidney, which leads to secondary aldosterone deficiency (hyporeninemic hypoaldosteronism); (2) inherited enzyme defects in aldosterone biosynthesis; and (3) acquired forms of primary aldosterone deficiency (post-surgical or due to heparin therapy). T e resulting metabolic changes are hyperkalemia and hyponatremia. Mild or moderate volume depletion, often with postural or unprovoked hypotension, may also occur. Nevertheless, isolated aldosterone deficiency is not as common as Addison disease.

Glucocorticoid Excess (Cushing Syndrome)

Endogenous Cushing syndrome is the result of autonomous excessive production of cortisol, leading to a characteristic set of clinical features, including (1) truncal obesity, (2) moon facies, (3) a "buffalo" hump on the upper back below the neck, (4) supraclavicular fat pads, (5) purple striae, (6) myopathy, (7) hypertension, (8) hirsutism, (9) hypokalemic alkalosis, (10) carbohydrate intolerance, (11) secondary osteoporosis, (12) disturbed reproductive function, and (13) neuropsychiatric symptoms. Exogenous Cushing syndrome is caused by excessive oral or parenteral glucocorticoid therapy.

Endogenous disorders that cause hypersecretion of cortisol and Cushing syndrome (Figure 41-7) may be classified as ACTH dependent or ACTH independent. Cushing disease is the pituitary-dependent form of Cushing syndrome. In Cushing disease, hypersecretion of ACTH by an anterior pituitary tumor leads to bilateral adrenal hyperplasia and cortisol overproduction. In the ectopic ACTH syndrome, nonendocrine

tumors develop the ability to secrete ACTH, resulting in (1) bilateral adrenal hyperplasia, (2) unregulated cortisol secretion, and (3) suppression of pituitary ACTH release. Rarely, does ectopic secretion of CRH occur. In ectopic ACTH syndrome, the patient's clinical presentation is usually dominated by the presence of cancer, and the patient may not display classic clinical findings of Cushing syndrome, such as centripetal obesity. Ectopic Cushing syndrome due to a bronchial carcinoid has been known to mimic classical Cushing disease and present a diagnostic dilemma requiring measurements of hormones in blood obtained from the inferior petrosal venous sinus.

Multiple endocrine neoplasia type 1 (MEN1) is part of a group of disorders that affect the endocrine system through development of neoplastic lesions in the (1) pituitary, (2) parathyroid gland, and (3) pancreas. It is an uncommon cause of Cushing syndrome. Excess cortisol production when seen in MEN1 is most commonly attributable to hypersecretion of ACTH from a pituitary microadenoma.

Cushing syndrome is an uncommon disorder, but it must be considered frequently as many of the usual signs and symptoms of this syndrome are seen commonly in patients. The initial diagnosis of Cushing syndrome, particularly in mild or early disease, rests on laboratory evidence of excessive and autonomous cortisol production. The following three screening tests are available for detecting Cushing syndrome: (1) measurement of 24-hour UFC, (2) overnight dexamethasone suppression test, and (3) midnight measurements of salivary or serum/plasma cortisol. The most reliable screening test is measurement of 24-hour urine free cortisol excretion.[7]

Congenital Adrenal Hyperplasia

CAH is the most common cause of adrenocortical insufficiency in newborns. It is discussed under adrenal hormone overproduction syndromes, because CAH commonly leads to overproduction of adrenal androgens. Thus, as noted previously, CAH presents a mixed picture of cortisol deficiency (hypofunction) and adrenal androgen overproduction (hyperfunction).

CAH results from loss-of-function mutations in specific adrenocortical enzymes that are responsible for the synthesis of cortisol. These disorders are inherited as autosomal recessive traits. Six enzymes are necessary for the conversion of cholesterol into cortisol, and deficiencies of five of these enzymes have been described. However, 95% of CAH cases are due to deficiency in CYP21, also called 21α-hydroxylase; most of the remaining cases are due to CYP11B1 (11β-hydroxylase) deficiency. Other causes of CAH are rare. The incidence of 21α-hydroxylase CAH in Western societies varies from 1 in 5000 to 15,000 live births. Neonatal screening for 21α-hydroxylase–deficient and 11β-hydroxylase–deficient CAH in newborns by measuring 17α-hydroxyprogesterone (17-OHP) is practiced in the United States and many other countries. 17-OHP measurements are more sensitive for the detection of 21α-hydroxylase–deficient CAH than 11β-hydroxylase–deficient CAH. Because CAH produces elevations of adrenal androgens (DHEA and androstenedione) in utero, virilization of the external genitalia of the female fetus occurs, producing sexual ambiguity. Inadequate male sexual development occurs in rare forms of CAH due to deficiencies of 3β hydroxysteroid dehydrogenase or 17-hydroxylase (CYP17).

Rarely, traumatic adrenal hemorrhage or adrenal hemorrhage from sepsis (**Waterhouse-Friderichsen syndrome**) causes adrenal failure in newborns.

Cortisol deficiency in affected individuals leads to (1) malaise, (2) failure to thrive, (3) hypoglycemia, and (4) vascular instability. In approximately one half of infants afflicted with 21α-hydroxylase–deficient CAH, insufficient aldosterone production causes (1) hyponatremia, (2) hyperkalemia, (3) acidosis, (4) dehydration, and (5) hypotension. In its most severe form, this type of "salt-losing" 21α-hydroxylase–deficient CAH patients clinically present at 10 to 14 days of age with Addisonian crisis. Untreated, mortality is very high in salt-losing 21α-hydroxylase deficiency. The non–salt-losing form of this disease is customarily referred to as simple virilizing 21α-hydroxylase deficient CAH.

Functioning Adrenocortical Tumors

Increased concentrations of (1) plasma DHEA-S, (2) DHEA, (3) androstenedione, and (4) testosterone are seen in patients with virilizing adrenal adenomas and Cushing syndrome. The plasma concentrations of DHEA may also be increased in women with virilizing ovarian tumors. CT scans along with MRI are useful in differentiating the sites of the tumors (e.g., ovarian versus adrenal).

Aldosterone-producing adenomas, referred to as **Conn syndrome**, are typically small microadenomas found in the zona glomerulosa that hypersecrete aldosterone, producing the syndrome characterized by low renin, hypokalemic alkalosis, and hypertension.

Adrenal carcinomas are rare, with an incidence of only 1 per million population, and occur more commonly in women than in men by a 2.5:1.0 ratio. Most adrenal carcinomas are functional, producing glucocorticoids alone or both glucocorticoids and androgens. Plasma DHEA-S, DHEA, and androstenedione concentrations are markedly increased in patients with functional adrenal carcinomas. The peripheral conversion of adrenal androgens to testosterone results in hirsutism and virilization. Concentrations of DHEA-S often exceed 10 μg/mL in patients with adrenal carcinoma and usually are diagnostic for this malignancy. Feminizing adrenocortical carcinomas are also rare. These tumors produce increased concentrations in plasma of (1) DHEA-S, (2) DHEA, (3) androstenedione, (4) estrone, and (5) estradiol, Gynecomastia and sexual dysfunction occur in males, and precocious pseudopuberty occurs in prepubertal females.

Nonfunctioning Adrenocortical Tumors

Approximately 2% of the human population has an adrenal mass; most of these tumors are nonfunctioning and benign and are called incidentalomas when found during imaging studies conducted to investigate unrelated signs and symptoms.[1] The tumors usually are found when a CT or MRI scan of the abdomen is performed that easily detects tumors 1 cm in diameter or 5 g in weight. No virilizing tumors smaller than

1 cm in diameter have been reported. Carcinomas usually weigh more than 30 g. An unexpected finding of an adrenal mass is investigated by clinical examination of the patient for signs of adrenal cortical hormone action. Laboratory evaluation includes tests for cortisol and aldosterone, plus tests to rule out tumors of the adrenal medulla.

Mineralocorticoid Excess (Hyperaldosteronism)

Primary **hyperaldosteronism**, a syndrome of adrenal hypersecretion of aldosterone by the adrenals, is an increasingly recognized, treatable cause of hypertension. In primary hyperaldosteronism, excessive aldosterone production originates within the adrenal gland. The most common causes are aldosterone producing adenoma and bilateral idiopathic hyperplasia. In secondary hyperaldosteronism, a stimulus outside the adrenal gland activates the renin-angiotensin system. The interactions of (1) renin, (2) angiotensin, and (3) aldosterone are important in the regulation of extracellular fluid volume and blood pressure, and in regulating the balance of sodium and potassium ions as well as acid-base balance.

Secondary hyperaldosteronism is suspected in patients with (1) volume depletion, (2) edema, and (3) hypokalemic alkalosis. Hypertension is present in primary hyperaldosteronism, but it is usually absent in secondary hyperaldosteronism, unless the patient has a reninoma (renin-secreting tumor) or renal artery stenosis. Measurements of renin and aldosterone concentrations are seldom needed in cases of secondary hyperaldosteronism, because precipitating circumstances that explain the patient's hypokalemia and alkalosis (e.g., secondary hyperaldosteronism is expected in congestive heart failure) are apparent. Renin and aldosterone measurements are essential, however, in the investigation of primary disturbances in the renin-angiotensin-aldosterone system and in the assessment of renal artery stenosis.

In suspected primary hyperaldosteronism a useful screening test is the plasma aldosterone concentration (PAC)/PRA ratio. If the PAC/PRA is greater than 20 to 25, the presumptive diagnosis of primary aldosteronism is established, and confirmation with dynamic tests should be sought.

Hypokalemia is the key clinical finding that primary hyperaldosteronism may be present in a patient with diastolic hypertension. To confirm the diagnosis, it is necessary to demonstrate (1) hyposecretion of renin that is not appropriately corrected during volume depletion, and (2) hypersecretion of aldosterone that fails to suppress appropriately during volume expansion. Figure 41-8 shows a suggested scheme for evaluating patients with suspected mineralocorticoid excess.

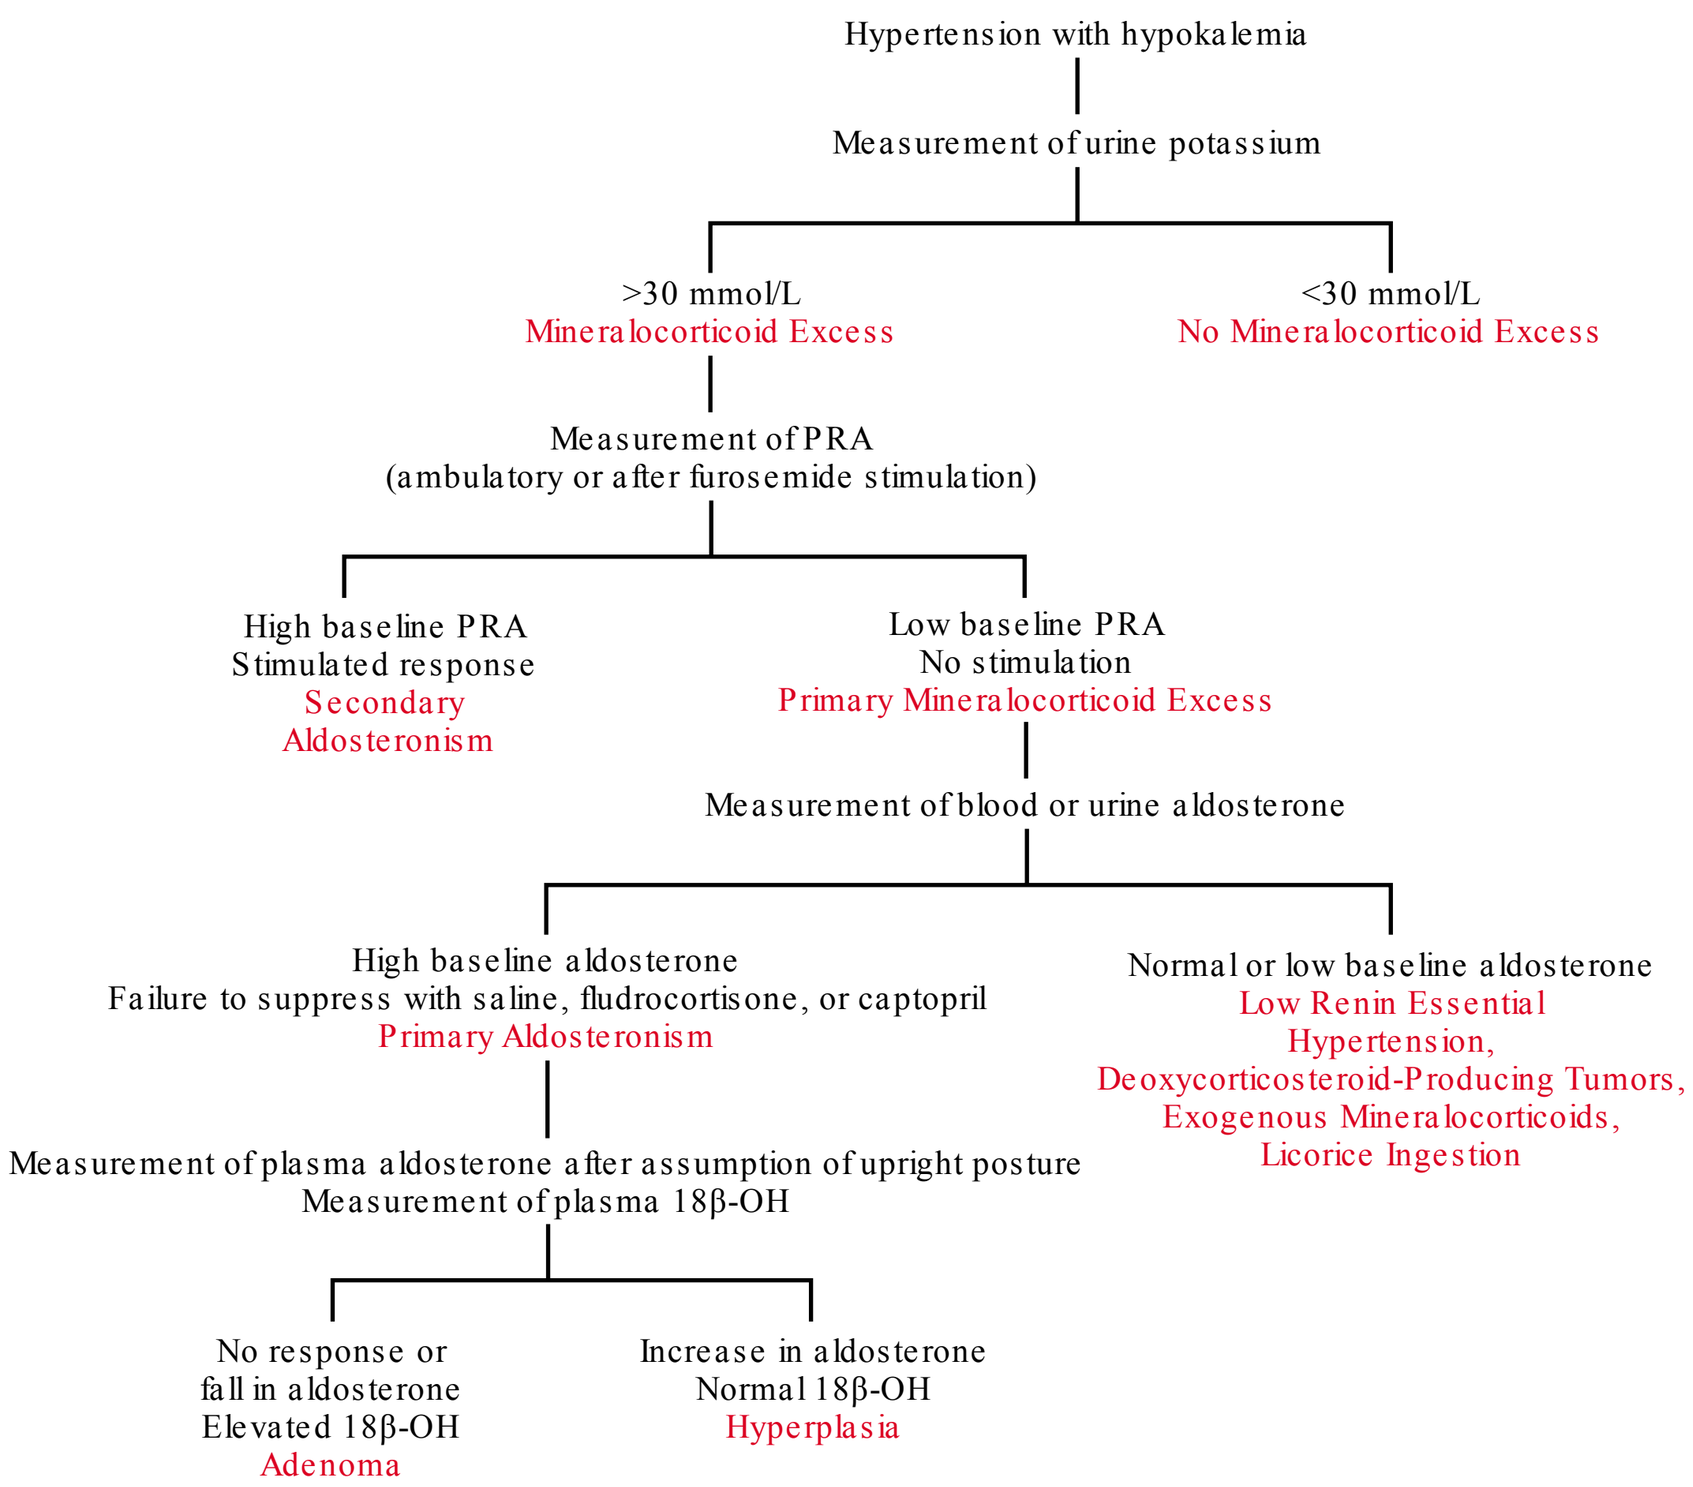

Figure 41-8 Scheme for the laboratory work-up of suspected aldosteronism causing hypertension. 18β-OH, 18β-hydroxycorticosterone; PRA, plasma renin activity.

In specialized centers, measurements of aldosterone concentrations in the veins that drain the left and right adrenal glands are used before surgical treatment to determine which adrenal is responsible for the hyperaldosteronism (presumably from an adenoma), or if the secretion shows no "lateralization."

Laboratory Evaluation of Adrenocortical Function

Laboratory evaluation of adrenal cortex function centers on measurement of (1) cortisol, the primary glucocorticoid; (2) aldosterone, the primary mineralocorticoid; and (3) androgens, of which the adrenal cortex is a primary source in females and minor source in males. Chromaffin cells in the adrenal medulla are a source of catecholamines, which are discussed in Chapter 26.

Choice of Specimen

Steroid hormones are measured in (1) urine, (2) blood, (3) saliva, and (4) hair. The choice of specimen depends on the application. For clinical assessment of adrenal function, blood (plasma or serum) measurements are convenient, but conditions that cause the binding protein concentration to increase may produce clinically benign elevations in the total cortisol concentration. Urinary concentrations are helpful in determining time-integrated hormone production and provide useful estimates of free hormone concentrations in blood if an appropriately timed urine specimen collection is available. Measurement of steroid hormones in saliva has been proposed as an alternative to urinary hormone assays to estimate free hormone concentrations in blood, the principal advantage being ease of collection of saliva.[19] Hair analysis may be useful for assessing adrenal hormone production over an extended period of time, but currently hair testing is not in widespread use.

Urine

Urinary excretion of a hormone, or its metabolites, provides an approximation of the amount secreted over the time the urine is collected, typically 24 hours. Thus, urinary hormone or metabolite measurements are useful when the hormone has a very short biological half-life and/or its secretion is pulsatile or varies in predictable cycles. Timed urine collections suffer variability associated with factors, such as completeness of collection and impaired renal function.

Blood

Circulating concentrations of steroids in the blood provide the most direct measure of hormone secretion. Provocative testing (stimulation and suppression tests, discussed earlier) often require blood samples to study the rapid changes that occur in hormone concentrations. Many of the steroid hormones are released in a pulsatile or rhythmic fashion, so their concentrations in an isolated blood specimen should take into account these variables.

Mineralocorticoid and adrenal androgen secretion is circadian and episodic in nature, but the dynamic swings in concentration are not as pronounced as with cortisol. It is usually recommended, however, that blood samples for adrenal steroids be collected between 0700 and 1000 for consistency in interpreting the results, particularly when comparing to reference intervals.

Steroid hormone concentrations are nearly the same in serum and plasma. It has been suggested that steroid hormone concentrations may change in unseparated blood specimens as the result of 17β-hydroxysteroid dehydrogenase activity in red blood cells and macrophages, but stability studies of (1) estradiol, (2) cortisol, (3) testosterone, (4) progesterone, (5) 17α- hydroxyprogesterone, androstenedione, and (6) DHEA-S have failed to reveal any clinically significant changes in these hormones in whole blood specimens stored at room temperature for up to 1 week.[10]

Saliva (Oral Fluid)

Most steroids of clinical interest have been measured in saliva, and for some steroids, such as (1) cortisol, (2) estriol, and (3) progesterone, salivary concentrations appear to correlate with the free hormone concentration in plasma. For other steroids, such as (1) testosterone, (2) 17α-hydroxyprogesterone, (3) estradiol, and (4) aldosterone, the clinical usefulness of salivary measurements is yet to be established.

Measurement of steroids in saliva is attractive because specimens are simple to collect; this consideration is particularly important in pediatric patients. Several saliva collection devices using absorbent materials have been designed to collect a sufficient volume of saliva for steroid analysis. However, recovery of cortisol from these devices has been questioned. Collection of saliva specimens using cotton swabs, cotton ropes, and hydrocellulose microsponges has been reported, but cortisol measurements in saliva specimens collected with these devices are more variable than measurements in directly collected ("passive drool") saliva specimens. Salivary cortisol concentrations measured around midnight are usually <0.15 μg/dL.

Analytical Methods

Immunometric, chromatographic and combined chromatographic/mass-spectrometric methods are available for measuring steroid hormones. Methods for measuring several of these hormones are discussed below.

Measurement of Total Cortisol

Approximately 90% of circulating cortisol is bound to plasma proteins, primarily to CBG. Cortisol also binds weakly to albumin. The concentration of CBG in the plasma increases in hyperestrogenic states, including pregnancy and oral contraceptive use; therefore total cortisol in serum is increased in these conditions, although free cortisol remains within normal limits. Immunoassays for direct measurement of cortisol have mostly replaced extraction/chromatographic methods for routine cortisol determinations.

Immunoassay

Immunoassays are the most commonly used methods for measuring cortisol in serum and urine, and are widely available

on various automated immunoassay platforms. Most cortisol immunoassays in routine use are heterogeneous, competitive-binding assays that require no initial extraction of steroids from the specimen. Cortisol is displaced from CBG and other endogenous binding proteins by (1) protein-binding agents, such as ANS or salicylate, (2) low pH, or (3) heat treatment. The efficiency of cortisol displacement from proteins by agents (such as, ANS) may be influenced by the concentration of binding proteins in the specimen; the amount of ANS that is adequate for plasma obtained from healthy men and nonpregnant women may be insufficient to completely displace cortisol from CBG in pregnancy when CBG concentrations are increased.

Most contemporary automated cortisol immunoassays use nonisotopic labels. Enzyme labels used in these immunoassays include (1) horseradish peroxidase, (2) alkaline phosphatase, or (3) β-galactosidase. The products generated from these assays are measured using (1) photometric, (2) fluorescent, or (3) chemiluminescent labels and detectors. Nonenzymatic approaches involve fluorescent and chemiluminescent labels, and these are the most common methods currently in use. Both heterogeneous and homogeneous designs have been developed. Most current heterogeneous immunoassays for cortisol involve chemiluminescent labels and magnetic separation. Homogeneous immunoassays for cortisol include the enzyme-multiplied immunoassay technique (EMIT) and the cloned enzyme donor immunoassay (CEDIA).

Chromatographic Methods

Chromatographic methods used to measure cortisol include (1) gas chromatography (GC), (2) thin-layer chromatography (TLC), (3) high performance liquid chromatography (HPLC), and (4) GC and HPLC coupled to mass spectrophotometric detectors (GCMS, LCMS, and LCMSMS). Methods using these latter detectors provide the most specific methods for measuring corticosteroids. Cortisol methods based on capillary electrophoresis are also available. All of these methods demonstrate high specificity for cortisol but have relatively low throughput and require sample preparation steps before analysis. For example, most HPLC methods require preanalytical extraction of cortisol with solid-phase extraction columns or liquid-liquid extraction prior to separation and detection by reversed- or normal-phase HPLC and a fluorescence or ultraviolet absorption detector. GCMS methods for cortisol typically require extraction of the hormone from plasma and conversion to the methoxime-trimethylsilyl derivative prior to analysis. Deuterated cortisol is available for use as the internal standard in MS.

Liquid chromatography/tandem mass spectrometry (LCMSMS) methods are becoming increasingly common. Liquid chromatography has the advantage of not requiring volatile derivatives, so specimen preparation is vastly simplified. LCMSMS methods have been developed that measure cortisol, corticosterone, and multiple corticosteroids.[6] LCMSMS appears poised to become the method of choice for corticosteroid measurements.

Specimen Collection and Storage

Cortisol is measured in (1) serum, (2) heparinized plasma, or (3) EDTA plasma; although some methods avoid EDTA plasma because of assay interference. In serum or plasma specimens, cortisol is stable for 7 days at room temperature or refrigerated, and it is stable for 3 months frozen at −20 °C.

Comments

Blood cortisol concentrations parallel ACTH concentrations with episodic and diurnal minima and maxima observed throughout the day. The cortisol concentration in the evening is normally less than 50% of the morning cortisol concentration. Increased cortisol is associated with (1) stress, (2) glucocorticoid therapy, (3) pregnancy, (4) depression, and (5) hypoglycemia. No significant difference in cortisol concentrations has been noted between males and females, and reference intervals for cortisol are not age dependent. The half-life of cortisol in the circulation is approximately 60 minutes, so concentrations of this hormone in blood change rapidly. In newborns, a transient increase in cortisol occurs immediately after birth, but after 12 to 48 hours, cortisol declines to concentrations below umbilical cord blood concentrations. It then increases to a stable reference interval by about 1 week of age. Renal failure does not directly affect serum cortisol, but metabolites that are not cleared in the urine have the potential to cross-react with immunoassays, causing overestimation of blood cortisol concentrations. Extraction of cortisol into an organic solvent may eliminate interference from hydrophilic metabolites. Celite chromatography has been used to "clear" the sample of possible interference before immunoassay measurements are carried out in patients with renal failure.

Measurement of Free Cortisol

Various methods have been developed to measure the free fraction of cortisol in serum, including (1) ultrafiltration, (2) equilibrium dialysis, and (3) gel filtration. These assays, however, are technically complex and expensive, and are not in general use. Algorithms have been suggested for estimating the free cortisol concentration based on CBG and albumin concentrations.[11] Measurement of urinary cortisol provides an estimate of the free hormone concentration and for many years has been considered the best screening test for Cushing related disease, although salivary (oral fluid) cortisol has been recommended as the first-line diagnostic test. Approximately 2% of total cortisol is excreted in the urine, and urinary cortisol may be used as a screening test for cortisol hypersecretion. However, β-hydroxycortisol also appears in the urine and may interfere with some immunoassays used to measure cortisol in urine.

Methods

Salivary cortisol reflects the concentration of free cortisol in blood, and measurement of cortisol in saliva (i.e., oral fluid) is a practical and convenient way to assess the free hormone concentration. Most immunoassays for total serum cortisol have been used to measure cortisol in saliva. Extraction for these assays

is not required because saliva contains virtually no cortisol-binding proteins or other cortisol metabolites. The glycoproteins in saliva are precipitated by freezing and thawing followed by centrifugation, producing a clear fluid that is free of protein interference. In some protocols, 10 minutes prior to obtaining the salivary cortisol sample, the subject is required to rinse their mouths with water. Any oral bleeding can increase the salivary cortisol concentration, because blood has much higher concentrations of cortisol than saliva, reflecting the higher concentrations in blood of proteins that bind cortisol.

Immunoassays designed to measure total serum cortisol have been used to measure urinary (free) cortisol provided that cortisol metabolites and conjugates that cross-react with the anti-cortisol antibodies are first removed by liquid/liquid or solid phase extraction. Unextracted urine may be assayed for cortisol if the antibody has sufficient selectivity, although reference values may differ from those seen in methods that include an extraction step. Even with solvent extraction, most commercial assays for cortisol in urine are subject to interference and imprecision. Chromatographic procedures (such as HPLC) are more specific than immunoassays for measuring urinary cortisol; LCMSMS is the preferred method.

Specimen Collection and Storage

A 24-hour urine specimen should be collected with 10 g of boric acid to maintain the urine pH below 7.5, and the urine should be refrigerated during the collection period (for example, the sample is placed on ice in a disposable Styrofoam ice chest). After the total volume of urine is measured, a thoroughly mixed aliquot may be stored at −20 °C prior to analysis. Care should be taken to ensure an appropriately timed, complete 24-hour collection, because an incorrectly timed sample is the largest source of error with this method. Cortisol measurements on randomly collected urine specimens are not useful. One report described falsely increased urinary cortisol results attributed to interference from carbamazepine.[18] The drug interfered with the liquid chromatography method used for measuring urinary cortisol. It was also speculated that CYP3A4 induction by carbamazepine affected the results of the low-dose dexamethasone suppression test through enhanced metabolism of dexamethasone.

Cortisol is stable in saliva for 1 week at 4 °C and for 4 months when stored frozen. Freezing of specimens is recommended, because it leads to precipitation of salivary glycoproteins and produces a nonviscous liquid supernatant that makes volumetric transfer by pipette more reliable.

Measurement of Aldosterone

Measurement of aldosterone is technically challenging, because the concentration of this hormone in blood is very low, nearly one thousandth that of the cortisol concentration.

Methods

Immunoassays for measuring aldosterone in blood and urine are available. Radioimmunoassay methods for measuring aldosterone ordinarily use antibodies generated against an aldosterone-3-mono-oxime-bovine serum albumin (BSA) conjugate, an 125I-labeled ligand, and ANS at pH 3.6 to displace aldosterone from binding proteins (primarily albumin). Although RIA methods for measuring aldosterone remain relatively common, nonisotopic immunoassays are becoming increasingly available.

The cross-reactivity of anti-aldosterone antibodies with other adrenal steroids, such as desoxycortisol and corticosterone is relatively low (<0.01%). However, the concentration of potentially cross-reacting steroids sometimes is very high, requiring some purification of aldosterone before measurement. Unconjugated plasma aldosterone is extracted into an organic solvent and purified by chromatography. The addition of tritiated aldosterone as an internal standard corrects for incomplete extraction. In urine, unconjugated steroids first are extracted into an organic solvent (such as ethyl acetate or methylene chloride) after acid hydrolysis of the conjugates. The solvent is evaporated, and the dried extract is reconstituted in a buffer before analysis. Whether the specimen requires purification depends on the diagnostic kit being used and the type of patient being evaluated. For example, specificity is not a significant concern in hypertensive adults without adrenal disease, whereas greater specificity may be needed for newborns and young infants, patients with adrenal disease, and pregnant women, in whom high concentrations of potentially interfering steroids are likely.

An automated heterogeneous immunoassay for aldosterone involving a monoclonal anti-aldosterone antibody and a chemiluminescent tracer has been validated against three RIA methods.[17] This method displays minimal (<0.05) cross-reactivity with (1) corticosterone, (2) cortisol, (3) 11- desoxycorticosterone, (4) 18-hydroxycorticosterone, and (5) dexamethasone, and it has a linear range of 15 to 1200 ng/L. A time-resolved fluorescence immunoassay for measuring aldosterone in saliva is available.[15] LC/MS-MS has also been applied to aldosterone measurements; these results were in close agreement with RIA measurements. The LC/MS-MS method had a detection limit of 69 pmol/L and linearity up to 5.5 nmol/L.

Specimen Collection and Storage

If possible, the patient should be in an upright position (standing or seated) for 30 to 120 minutes before collection because reference intervals were determined with use of samples from ambulatory subjects. Plasma (heparin or EDTA) or serum is suitable for aldosterone measurement, although EDTA plasma is preferred. The aldosterone concentration in specimens stored at room temperature begins to decline after 24 hours, although little change in aldosterone was observed in unseparated blood specimens stored at 32 °C for 24 hours. The aldosterone concentration in refrigerated or frozen specimens is stable for at least 4 days. For urine assays, a 24-hour urine specimen should be collected with boric acid as a preservative.

Measurement of 17-Hydroxyprogesterone

The most common cause of CAH is a deficiency in the 21α-hydroxylase enzyme (CYP21), which converts 17-hydroxyprogesterone (17-OHP) to 11-desoxycortisol.

17-OHP may also be increased in CYP11B1-11β-hydroxylase deficiency CAH. Therefore, measurement of serum or plasma 17-OHP is used to diagnose the most common cases of CAH. In 21α-hydroxylase deficiency, 17-OHP concentrations may reach several hundred times the upper limit of the reference interval.

Methods

Radioimmunoassays for 17-OHP that use antibodies against 17-hydroxyprogesterone-3-carboxymethyloxime-BSA are available; these methods are used with (1) serum, (2) plasma, (3) saliva, and even (4) amniotic fluid. Monoclonal antibody-based methods have also been described. In addition to radioiodinated tracers, nonisotopic labels used in 17-OHP immunoassays include enzymes with (1) photometric, (2) fluorescent, or (3) chemiluminescent substrates, and fluorescence-based immunoassays using fluorescein or streptavidin-europium labels, and chemiluminescent labels. Despite the use of highly specific antisera, most immunoassays are susceptible to interference by other corticosteroids that may be present in neonatal and infant plasma specimens.

Methods for measuring 17-OHP in serum by GCMS and LCMSMS have been described. For chromatographic analysis, 17-OHP is typically extracted using a liquid-liquid (diethyl-ether/diethylacetate or methyl-tert-butyl-ether), solid-phase, or on-line extraction procedure; these methods have detection limits below 1 nmol/L. LCMSMS methods for measuring 17-OHP in dried blood spots obtained from neonates and in urine are also available.

Specimen Collection and Storage

Most reports of analytical methods for measuring 17-OHP use serum, although plasma has also been used. Specimens may be stored at 4 °C for up to 4 days or at −20 °C for up to 1 month. 17-OHP is stable in unseparated blood at room temperature for 1 week.

Screening newborns for 21α-hydroxylase deficiency has been possible since the introduction of 17-OHP immunoassays in 1977. Neonatal specimens are obtained by heel puncture and collected in capillary tubes or on filter paper. Dried blood specimens are (1) stable, (2) easily transported, and (3) are widely used to screen newborns for metabolic defects. It has been reported that the presence of EDTA in dried blood specimens may interfere with 17-OHP results measured by immunometric methods based on lanthanide fluorescence. 17-OHP may also be measured in saliva.

Measurement of 11-Desoxycortisol

Serum or plasma 11-desoxycortisol (compound S) measurements are used to detect 11β-hydroxylase (or CYP11B1 hydroxylase) deficiency or as part of the metyrapone stimulation test. Metyrapone inhibits the 11β-hydroxylase enzyme, and a 40- to 80-fold increase in plasma 11-desoxycortisol is observed after metyrapone stimulation in patients with normal pituitary-adrenal reserve. As a consequence, analytical methods for 11-desoxycortisol in the metyrapone stimulation tests do not require particularly high sensitivity.

Methods

Radioimmunoassay methods for the direct determination of plasma 11-desoxycortisol are available. Antiserum raised against 11-desoxycortisol-3-carboxymethyloxime-BSA has provided appropriate specificity with minimal cross-reactivity against other adrenal steroids. Some radioimmunoassay methods include an extraction step or column chromatography, or both. Nonisotopic methods for measuring 11-desoxycortisol in serum have been described, including (1) enzyme immunoassay, (2) fluorometric, and (3) fluorescence polarization methods. One method for measurement of 11-desoxycortisol involves the "open-sandwich enzyme immunoassay" technique, which is based on the reassociation of two cloned antibody variable regions by a bridging antigen.[13]

LCMSMS methods for measuring 11-desoxycortisol have been described, mostly as part of corticosteroid profiles. These methods typically include a liquid-liquid extraction into an organic solvent step, although solid-phase extraction has been used as well.

Specimen Collection and Storage

Most of the methods used for measuring 11-desoxycortisol have used serum, although use of plasma and urine are also used. The stability of 11-desoxycortisol in stored specimens has not been established.

Measurement of Renin Activity and Concentration

Circulating concentrations of prorenin may be as many as 100-fold greater than the concentration of renin (although a 10:1 ratio of prorenin to renin is more common); therefore even minimal cross-reactivity of prorenin with anti-renin antibodies used in direct immunoassays to measure renin is problematical.

Methods

Assays exist to measure PRA (by monitoring the production of angiotensin I) or the mass of renin by immunoassay. Each approach has advantages and disadvantages.

Renin Activity. Measuring renin activity (traditionally called plasma renin activity, or PRA) is a test of function that provides an indication of the biologically active fraction of renin in the specimen. It measures the primary function of the enzyme, which is the conversion of angiotensinogen to angiotensin I. In the test, angiotensinogen is provided by the patient's serum. Renin activity measurements, however, are difficult to standardize, and two general approaches are used to measure renin activity.

In the classic PRA method, inhibitors of angiotensinase and ACE are added to prevent the conversion of angiotensin I to angiotensin II (some methods "trap" angiotensin I with an antibody to prevent its conversion to angiotensin II), the specimen is incubated at 37 °C, and production of angiotensin I is measured. The rate of the renin-catalyzed production of angiotensin I is influenced by pH, incubation time, and, most importantly, the endogenous angiotensinogen concentration in the specimen, which is increased in (1) pregnancy, (2) glucocorticoid excess, and (3) estrogen administration. Because

the angiotensinogen concentration in blood does not ordinarily exceed the Michaelis–Menten term (Km) for the renin-angiotensinogen complex, its concentration is rate limiting. Therefore, the classic PRA method produces results that vary significantly, depending on the endogenous concentration of angiotensinogen.

In practice, a typical PRA method involves the preparation of two aliquots of plasma. One of the aliquots is incubated at 37 °C for 3 hours, and the other is kept at 4 °C (renin is not active at cold temperature). Following the incubation period, angiotensin I is measured by immunoassay in both aliquots, and the difference between the two reflects the renin activity, expressed as pg of angiotensin per mL of plasma generated per unit of time. The specificity of the PRA assay can be validated using plasma from anephric patients or deangiotensinized plasma.

A second approach to measure renin activity uses exogenous angiotensinogen as substrate and thereby avoids the variability associated with endogenous angiotensinogen concentrations. (Note: This approach is sometimes called plasma renin concentration assay, which is a confusing term in that the assay still involves the measurement of activity, rather than concentration. Furthermore, the term is not consistently applied; plasma renin concentration has been used to describe immunoassays that measure the renin concentration, rather than activity.) These renin activity methods use angiotensinogen derived from plasma collected from nephrectomized sheep; it is added at a concentration that is several times the K_m for the renin-angiotensinogen complex, ensuring that the reaction rate is limited by renin activity alone. An advantage of using a consistent source of angiotensinogen is that these activity assays are calibrated against renin reference materials. An International Reference Preparation of human renin (68/356), validated by bioassay, has been available from the WHO.

Prorenin exists in two forms, depending on whether the 46 amino acid "pro" segment is in an "open" or "closed" conformation. The open conformation of prorenin has the active site of the enzyme exposed, so this form is enzymatically active. In the blood, approximately 2% of prorenin is in the open conformation, but assay conditions (such as, cooling and low pH) will sometimes cause the closed conformation of prorenin to open, which results in an overestimate of physiologic renin activity. Incubation of plasma at 22 °C for 24 hours reversibly activates (unfolds) approximately 5% of prorenin, although incubation at 37 °C promotes refolding of the "pro" segment to its closed form. In some assays, the closed prorenin is deliberately opened by acidification (pH 3.3) or incubation with trypsin, which removes the "pro" segment from prorenin altogether. These assays measure total renin and prorenin by activating all of the prorenin and follow with a standard renin activity assay.

Angiotensin I and II. All renin activity assays rely on the conversion of angiotensinogen to angiotensin I or the subsequent production from angiotensin I of angiotensin II, the active form of the angiotensin hormone. Angiotensin II has a very short half-life (1 to 2 minutes) and is difficult to measure. Monoclonal antibodies with high affinity and specificity for angiotensin II have been produced. These antibodies have been used to develop a direct immunoassay for angiotensin II; as little as 0.8 fmol of angiotensin II in 2 mL of plasma has been detected without interference from angiotensin I. When angiotensinogen and ACE are in sufficient supply, however, the concentration of the prohormone angiotensin I is a reliable proxy for the renin activity and angiotensin II concentration in blood. Most angiotensin I methods involve radioimmunoassay, but (1) enzyme immunoassays, (2) HPLC, (3) fluorescence polarization and (4) mass spectrometric methods have also been described. A 2009 report described a homogeneous immunoassay for angiotensin I that is based on luminescent oxygen channeling, a technology involving chemiluminescence stimulated by photoexcited singlet oxygen.[5]

Renin Concentration. As an alternative to the PRA assays, the concentration of renin is measured by immunoassay. (These methods are sometimes called direct renin assays or mass assays.) A variety of monoclonal immunoradiometric assays (IRMAs) for renin have been developed, some of which measure renin and prorenin in the open configuration, and others of which measure all forms of renin and prorenin. Immunochemiluminometric (ICL) methods for renin are available, and the results of these assays have been correlated with IRMA results. One such assay involves a biotinylated capture antibody (which recognizes both renin and prorenin) immobilized to streptavidin-coated magnetic particles, and an acridinium ester–labeled signal antibody that recognizes only renin.[8] The chemiluminescent assay had a limit of detection of less than 0.1 mU/L and a limit of quantification of 2.6 mU/L with a CV <20%.

Direct renin immunoassays (both IRMA and ICL) show high correlation ($r = 0.98$) with renin activity assays. Direct renin results are expressed in mIU/L, and PRA results are expressed in $ng \cdot mL^{-1} \cdot h^{-1}$.

Specimen Collection and Storage

EDTA plasma is typically used for PRA assays. After centrifugation, plasma should be removed and frozen at −20 °C or below, although the renin concentration is stable in unseparated blood at room temperature for up to 6 hours. Plasma for PRA can be stored frozen up to 1 month before assay, but freeze-thaw cycles should be avoided because of the possible activation of prorenin. At the time of collection, blood should not be chilled or placed on ice because irreversible cryoactivation of prorenin may occur, leading to falsely high estimates of PRA. Serum or plasma samples collected in another anticoagulant have been used as long as EDTA is added (3 mmol/L) before incubation to inhibit ACE. Cryoactivation of prorenin, however, is more likely in serum than in plasma. Hemolyzed specimens should not be used because red blood cells contain angiotensinases.

If renin deficiency is suspected, the patient should be ambulatory for 30 minutes before blood collection. A 24-hour urine specimen for sodium is often collected on the day before the renin test to verify salt intake. Specimens with high renin activity can generate considerable amounts of angiotensin I before and during storage even at −20 °C. This will not affect results, however, if angiotensin I is measured with and without incubation.

Review Questions

1. Measurement of urinary free cortisol (UFC) is typically used as a screening test for:
   a. hyperaldosteronism.
   b. cortisol hypersecretion.
   c. adrenal insufficiency.
   d. congenital adrenal hyperplasia (CAH).
2. Glucocorticoids _____ blood glucose concentrations by altering synthesis of gluconeogenic enzymes.
   a. increase
   b. decrease
   c. do not affect
3. The primary mineralocorticoid is:
   a. cortisol.
   b. dehydroepiandrosterone (DHEA).
   c. 11-deoxycortisol.
   d. aldosterone.
4. The major site of steroid hormone metabolism that involves the P450 enzyme systems is the:
   a. liver.
   b. kidney.
   c. gastrointestinal tract.
   d. adipose tissue.
5. The stimulation test that is used to assess the ability of the adrenal glands to synthesize cortisol is referred to as the:
   a. dexamethasone test.
   b. metapyrone test.
   c. cosyntropin test.
   d. salt-loading test.
6. Primary adrenal insufficiency is referred to as:
   a. Cushing syndrome.
   b. Addison disease.
   c. Conn syndrome.
   d. congenital adrenal hyperplasia (CAH).
7. The adrenocortical disorder that results from loss-of-function mutations in specific adrenocortical enzymes that are responsible for the synthesis of cortisol is:
   a. Cushing syndrome.
   b. Addison disease.
   c. Conn syndrome.
   d. congenital adrenal hyperplasia (CAH).
8. The anterior pituitary hormone that is responsible for increasing the size and number of adrenocortical cells and for eventual cortisol synthesis is:
   a. corticotropin.
   b. growth hormone.
   c. corticotropin-releasing hormone (CRH).
   d. aldosterone.
9. One of the main functions of the mineralocorticoids is:
   a. increasing blood glucose.
   b. increased fat breakdown.
   c. sodium retention.
   d. glycogen synthesis.
10. Which one of the following disorders is the result of autonomous excessive production of cortisol?
    a. Cushing syndrome.
    b. Addison disease.
    c. Conn syndrome.
    d. congenital adrenal hyperplasia (CAH).

CHAPTER

42 Thyroid Disorders*

William E. Winter, M.D., Desmond Schatz, M.D., and Roger L. Bertholf, Ph.D.

Objectives

1. Define the following terms
   - Colloid
   - Cretinism
   - Euthyroid
   - Follicle
   - Goiter
   - Hashitoxicosis
   - Iodide
   - Reverse T_3 (rT_3)
   - Thyroglobulin (Tg)
   - Thyrotoxicosis
   - Thyroid storm
   - Thyrotropin-releasing hormone (TRH)
2. Describe the structure and function of the thyroid gland, including cell types, internal location of key hormone precursors and proteins, regulation of thyroid gland, and functions of the hormones synthesized and secreted.
3. Describe the metabolism of thyroid hormones, including synthesis, peripheral deiodination, specific effects on target tissues, and catabolism; state the full names of the thyroid hormones.
4. State the effects of increased and decreased thyroid hormones on thyroid-stimulating hormone (TSH), thyrotropin-releasing hormone (TRH), and target tissues.
5. For the following disorders, state the cause(s), symptoms, laboratory analyses, and lab results used to diagnose:
   - Autoimmune hypothyroidism
   - Graves disease
   - Hashimoto thyroiditis
   - hCG-induced hyperthyroidism
   - Myxedema
   - Primary and secondary hyperthyroidism
   - Primary and secondary hypothyroidism
   - Sick euthyroid syndrome
   - T_3 thyrotoxicosis
6. Name and describe the thyroid autoantibodies associated with thyroid disease, including mechanism of action, specificity of autoantibody to each disease, methods of detection and interferences.
7. State the methods, specimen requirements and problems with methods used to assess total and free thyroid hormones, thyroxine-binding globulin (TBG), thyroglobulin (Tg), and TSH.
8. State the formulae for estimation of free thyroid hormone concentration; given appropriate information, calculate estimates of free hormone concentration.
9. Analyze and solve case studies related to thyroid disease and laboratory analysis of these conditions.

Key Words and Definitions

Allan-Herndon-Dudley syndrome An X-linked syndrome caused by mutations in the SLC16A2 gene (locus: Xq13.2), which encodes a thyroid hormone transporter, and characterized by severe mental retardation, dysarthria, athetoid movements, muscle hypoplasia, and spastic paraplegia.

Apathetic hyperthyroidism A form of Graves disease that tends to affect mainly older adults who have stereotyped "senile" physical features and whose behavior is apathetic (indifferent) and inactive rather than hyperkinetic.

Autoimmune thyroid disease (AITD) Diseases in which the immune system attacks or stimulates the body's own thyroid gland.

Central hypothyroidism Refers to thyroid hormone deficiency due to a disorder of the (1) pituitary, (2) hypothalamus, or (3) hypothalamic-pituitary portal circulation.

Colloid An amorphous material found in the follicular lumen of the thyroid gland. A critical component is thyroglobulin (Tg).

Congenital hypothyroidism A pathological condition resulting from severe thyroid insufficiency, which may lead to cretinism or myxedema.

Cretinism An archaic term for the clinical consequences of untreated congenital hypothyroidism caused by a deficiency of thyroid hormone during prenatal development and infancy; characterized in childhood by short stature, developmental delay, dystrophy of the bones, and a low basal metabolism. Also called congenital myxedema which is also an archaic term.

Euthyroid Having normal thyroid function.

Euthyroid hyperthyroxinemia A condition characterized by increased concentrations of thyroxine in the blood but a normal concentration of thyroid-stimulating hormone and normal thyroid function.

*The authors gratefully acknowledge the contributions of Ronald J. Whitley and Laurence M. Demers to the chapter in the previous editions, on which portions of this chapter are based.

Key Words and Definitions—cont'd

Goiter An enlargement of the thyroid gland that causes a swelling in the front part of the neck.

Graves disease A disorder of the thyroid of autoimmune etiology that causes hyperthyroidism. Characterized by having at least two of the following conditions: hyperthyroidism, goiter, and exophthalmos. Also known in Europe as Basedow disease.

Hashimoto thyroiditis An autoimmune disorder in which the thyroid gland is attacked by a cell-mediated autoimmune process. Also known as Hashimoto disease and chronic lymphocytic thyroiditis, it is marked by (1) goiter, (2) chronic inflammation of the thyroid (thyroiditis), and (3) often hypothyroidism.

Hashitoxicosis Hyperthyroidism in patients with Hashimoto disease.

Hyperthyroidism A condition caused by excessive production of iodinated thyroid hormones. Symptoms and signs include increased basal metabolic rate, enlargement of the thyroid gland, rapid heart rate, high systolic blood pressure, and a number of secondary symptoms.

Hypothyroidism A condition of deficient thyroid gland activity leading to lethargy, muscle weakness, and intolerance to cold.

Myxedema A severe form of hypothyroidism in which there is accumulation of mucopolysaccharides in the skin and other tissue, leading to a thickening of facial features and a doughy induration of the skin.

Organification A process in the thyroid gland whereby iodide is oxidized and incorporated into tyrosyl residues (tyrosine) of thyroglobulin (Tg). Organification is catalyzed by the enzyme thyroperoxidase (TPO).

Pendrin A protein that is mutated in Pendred syndrome, which is an autosomal recessive disorder characterized by (1) sensorineural hearing loss, (2) goiter, and (3) a partial organification problem. Also known as the sodium-independent chloride/iodide transporter.

Primary hypothyroidism A condition that develops when the thyroid gland fails to produce or secrete as much thyroxine (T_4) as the body needs.

Reverse T_3 (rT_3) A biologically inert metabolite of thyroxine (T_4) with three iodine molecules attached in a configuration (L-3,3′,5′-triiodothyronine) different from that of the active thyroid hormone triiodothyronine (T_3).

Secondary hypothyroidism Hypothyroidism that arises as a consequence of inadequate secretion of thyroid stimulating hormone (TSH or thyrotropin) by the anterior pituitary gland.

Sick euthyroid syndrome Abnormalities of T_4, free T_4, T_3 and TSH concentrations that are seen in people with severe illness. In general, treatment with replacement thyroid hormone is not indicated.

Subclinical hyperthyroidism A biochemical condition with normal concentrations of serum thyroid hormones when the serum TSH concentration is repeatedly low in the absence of hypothalamic or pituitary disease.

T_3 Thyrotoxicosis A hyperthyroid condition in which T_3 but not T_4 is elevated.

Thyroglobulin (Tg) An iodine-containing glycoprotein of high molecular weight (663 kDa) present in the colloid of the follicles of the thyroid gland.

Thyroid follicle The secretory unit of the thyroid gland consisting of an outer layer of epithelial cells that enclose an amorphous material called colloid.

Thyroiditis A condition characterized by inflammation of the thyroid gland.

Thyroid-stimulating hormone (TSH) A polypeptide hormone synthesized by the anterior pituitary gland that promotes the growth of the thyroid gland and stimulates the synthesis and release of thyroid hormones by the thyroid gland. Also called thyrotropin.

Thyroid storm A life-threatening condition that develops in a minority of cases of untreated thyrotoxicosis (hyperthyroidism, or overactive thyroid).

Thyrotoxicosis A toxic condition resulting from excessive amounts of thyroid hormones in the body.

Thyrotropin-releasing hormone (TRH) A tripeptide produced in the hypothalamus that stimulates the synthesis and release of TSH from the anterior pituitary.

Thyroxine The major hormone synthesized and released by the thyroid gland that contains four iodine molecules (L-3,5,3′,5′-tetraiodothyronine).

Toxic multinodular goiter A condition in which the thyroid gland contains multiple lumps (nodules) that are overactive and that produce excess thyroid hormones. Also known as Parry disease and Plummer disease.

Transthyretin (TTR) A protein found in serum and cerebrospinal fluid that binds to and transports thyroxine (T_4). TTR complexes with retinol binding protein (RBP) to prevent its loss through the glomerulus by filtration. Was once called prealbumin, because it traveles faster than albumin on electrophoresis gels.

Triiodothyronine The biologically active form of thyroid hormone formed primarily outside of the thyroid gland by the peripheral deiodination of thyroxine (T_4). Has three iodine molecules attached to its molecular structure (L-3,5,3′-triiodothyronine).

The thyroid gland is a butterfly-shaped gland located in the front of the neck just above the trachea in the adult human (see Figure 25-1, Chapter 25, page 431). The fully developed thyroid gland in a human weighs approximately 15 to 20 g. However, in disease states, the gland may weigh up to several hundred grams. The thyroid is composed of two lobes with the right lobe being somewhat larger than the left lobe. The lobes are connected by the isthmus.

The **thyroid follicle** or acinus (Figure 42-1) is the secretory unit of the thyroid gland. Each follicle has an outer layer of epithelial cells that enclose an amorphous material called **colloid** that is s mainly composed of **thyroglobulin (Tg)**. The important reactions of thyroid hormone synthesis, such as iodination and the initial phase of hormone secretion (colloid resorption into the cells), are believed to take place at or near the surface of the epithelial cells in the colloid.

The thyroid gland also contains another type of cell known as parafollicular or C cells. These cells have been shown to produce the polypeptide hormone calcitonin. These cells are confined within the follicular basement lamina or exist in clusters in the interfollicular spaces.

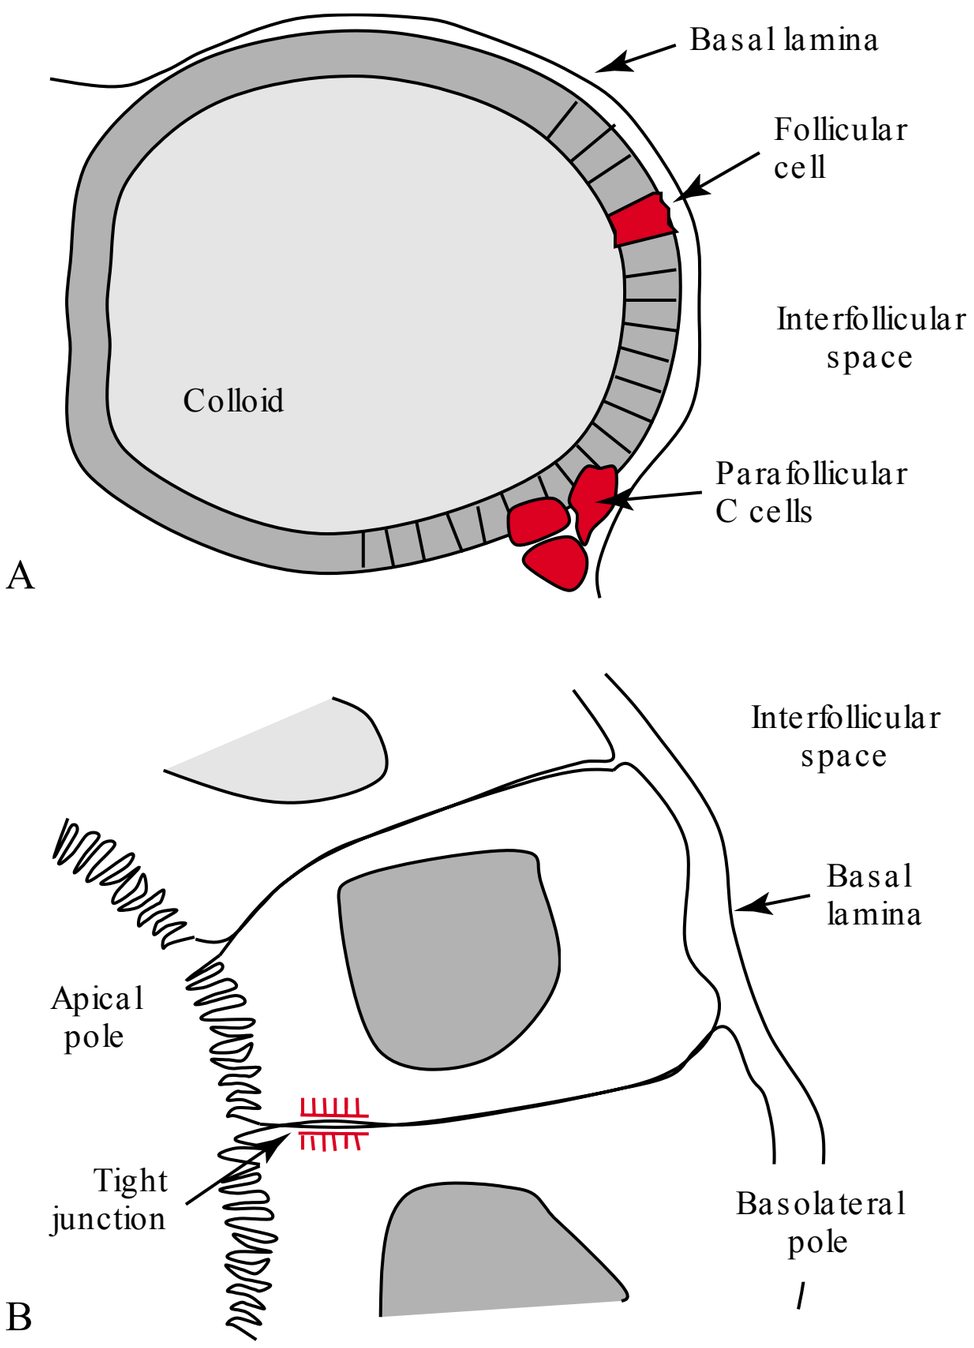

Figure 42-1 A, Basic unit of the thyroid gland. The follicle is the basic unit of the thyroid gland. It is composed of thyroid follicular cells surrounding the colloid. Outside the follicular cells is a basal lamina. Parafollicular (C cells) that secrete calcitonin can be found beneath or outside the basal lamina. Not pictured, between the follicles are capillaries and fbroblasts. B (inset image), Apical and basolateral poles of the follicular cells and tight junctions between the follicular cells.

Thyroid Hormones

The thyroid gland secretes two hormones, **thyroxine** (3,5,3′,5′-L-tetraiodothyronine) and **triiodothyronine** (3,5,3′-L-triiodothyronine), which are commonly known as T_4 and T_3, respectively (Table 42-1). In addition, the thyroid gland secretes very small amounts of biologically inactive 3,3′,5′-L-triiodothyronine (**reverse T_3 [rT_3]**) and minute quantities of monoiodotyrosine (MIT) and diiodotyrosine (DIT), which are precursors of T_3 and T_4. The structures of these compounds are shown in Figure 42-2.

Biological Function

The functions of thyroid hormones include (1) control of the basal metabolic rate and calorigenesis, (2) enhancement of mitochondrial metabolism, (3) stimulation of neural development and normal growth, (4) promotion of sexual maturation, (5) stimulation of adrenergic activity with increased heart rate

TABLE 42-1 Nomenclature and Abbreviations for Thyroid Tests

Hormone Concentration	
Total thyroxine	T_4
Total triiodothyronine (3,5,3′-triiodothyronine)	T_3
Free thyroxine	FT_4

and myocardial contractility, (6) stimulation of protein synthesis and carbohydrate metabolism, (7) increasing the synthesis and degradation of cholesterol and triglycerides, (8) increasing the requirement for vitamins, (9) increasing the calcium and phosphorus metabolism, and (10) enhancing the sensitivity of adrenergic receptors to catecholamines. These effects are typically magnified in patients with either an overactive thyroid gland (such as in **hyperthyroidism**), or reduced in patients with reduced thyroid function (such as, **hypothyroidism**).

Biochemistry

Approximately 40% of secreted T_4 is deiodinated in peripheral tissues by enzyme deiodinases to yield T_3, and about 45% is deiodinated to yield rT_3, a biologically inactive metabolite. Therefore, with normal T_4 production of ~100 nmol (approximately 80 μg) daily, approximately 40 nmol (26 μg) of T_3 and 45 nmol (29 μg) of rT_3 are produced by peripheral deiodination. From the estimated daily production rates for T_3 (30 μg) and rT_3 (30 μg) in a normal (**euthyroid**) state, at least 85% of T_3 production and essentially all of rT_3 production are accounted for by peripheral deiodination of T_4 rather than by direct secretion from the thyroid gland T_3 is at least four to five times more potent in biological systems than T_4. Because one third of all T_4 is converted to T_3 during the course of its metabolism, T_4 may be considered to be a prohormone for T_3.

The biosynthesis of thyroid hormones occurs by a process termed "**organification**" It involves the (1) trapping of circulating iodide by the thyroid gland, (2) incorporation of iodine into thyroglobulin tyrosines producing monoiodinated tyrosines and di-iodinated tyrosines, and (3) coupling of two iodinated tyrosyl residues to form the thyronines (T_4 and T_3) within the protein backbone of the thyroglobulin (Tg) protein in the follicular lumen. (Figure 42-3). Endocytosis followed by proteolytic cleavage of Tg releases the iodothyronines into the circulation.

Dietary iodine is the basic element involved in the synthesis of thyroid hormones. It is normally ingested in the form of iodide. Iodide transport to the follicles is the first and rate-limiting step in the synthetic process. The follicular cells of the thyroid concentrate iodide to some 30 to 40 times the normal plasma concentration by means of an energy-dependent pump mechanism, the sodium-iodide symporter (appoved gene name:solute carrier family 5 (sodium/iodide cotransporter), member 5; approved symbol SLC5A5; chromosome 19p13.11).

The synthesis of MIT and DIT (Figure 42-4), T_4 (Figure 42-5), and T_3 Figure 42-6), occurs mainly at the follicular cell–colloid interface but also within the colloid (Figure 42-3). Tg is present in highest concentrations within the colloid, where it is stored. The follicular cells engulf colloid globules by

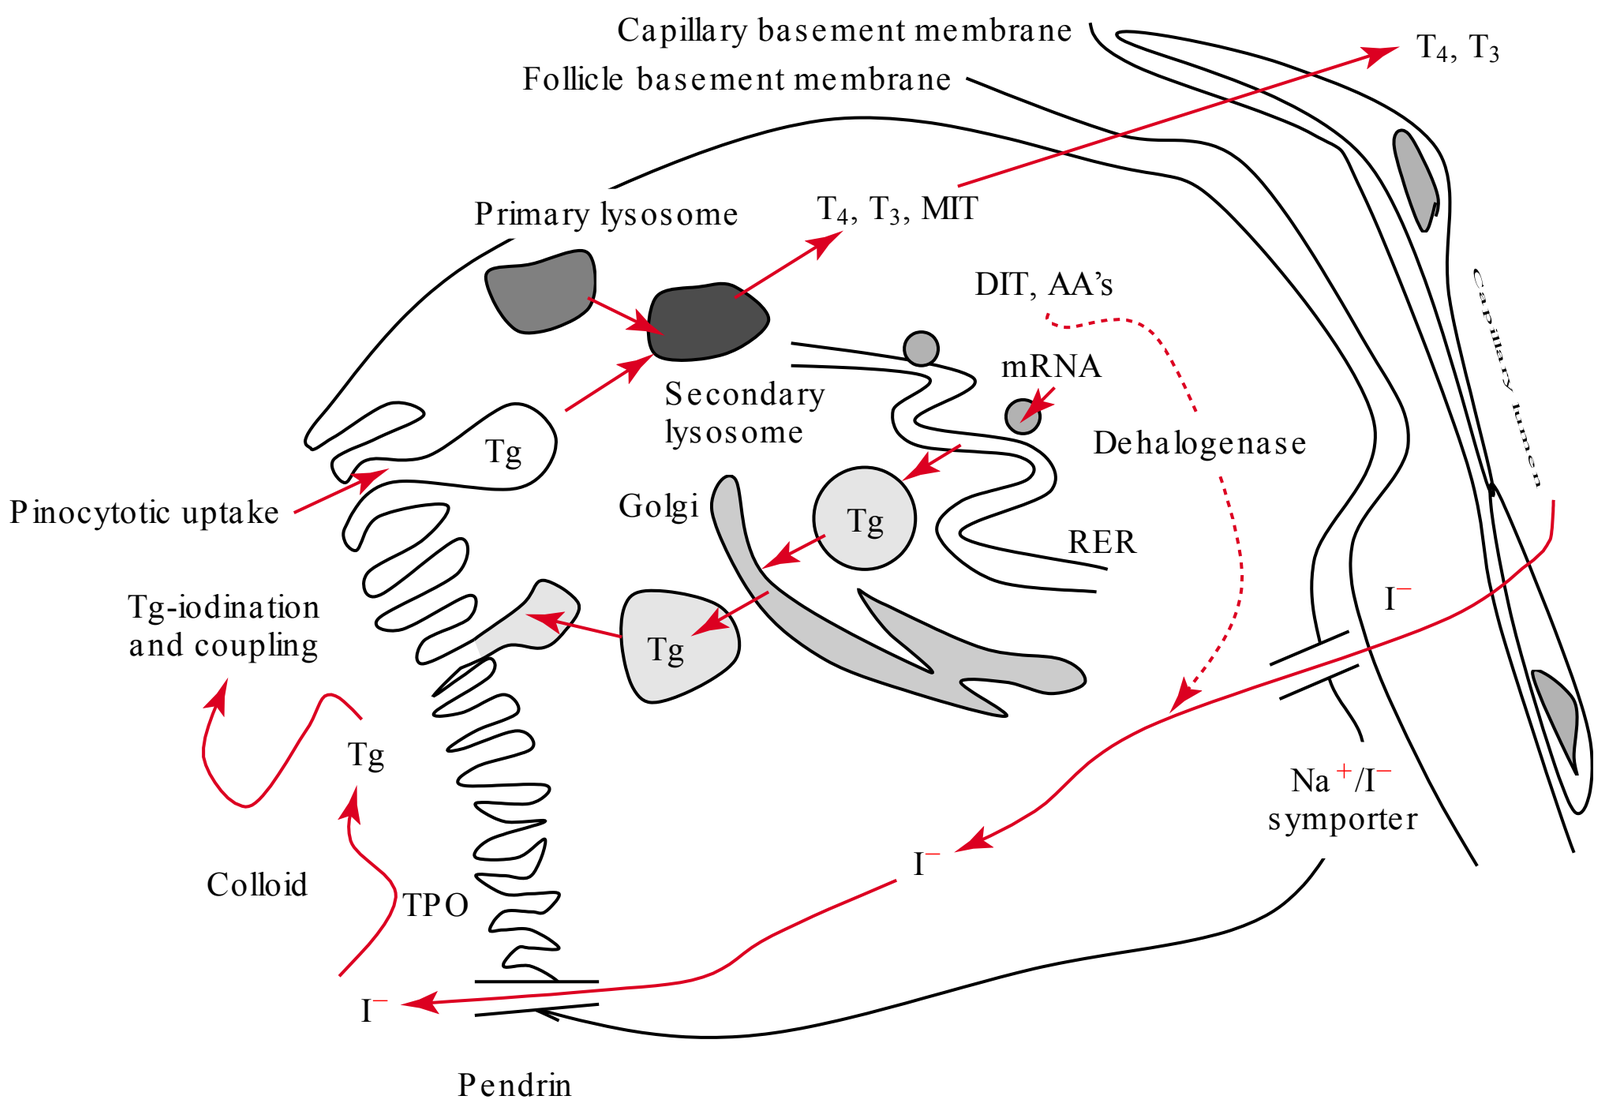

Figure 42-3 Synthesis of thyroid hormones begins with absorption of iodide by the thyroid follicular cell and the Na^+/I^- symporter (NIS). From the cytoplasm, iodide moves into the lacunae via pendrin. Within the lacunae, thyroperoxidase (TPO) and the dual oxidases [DUOX (not depicted)] convert iodide to iodine, leading to iodination of tyrosine residues on thyroglobulin (Tg). Tg is synthesized in the cell and exported to the lacunae. TPO is responsible for the coupling of monoiodotyrosine (MIT) and di-iodotyrosine (DIT) to form T_3, and di-iodotyrosine and di-iodotyrosine to form T_4. Upon uptake of iodinated Tg (containing T_4 and T_3) and fusion of this phagosome-like vesicle with a primary lysosome, Tg is degraded in a secondary lysosome, releasing T_4 and T_3 into the circulation and MIT and DIT undergo deiodination via a dehalogenase to recycle the iodine for new thyroid hormone synthesis.

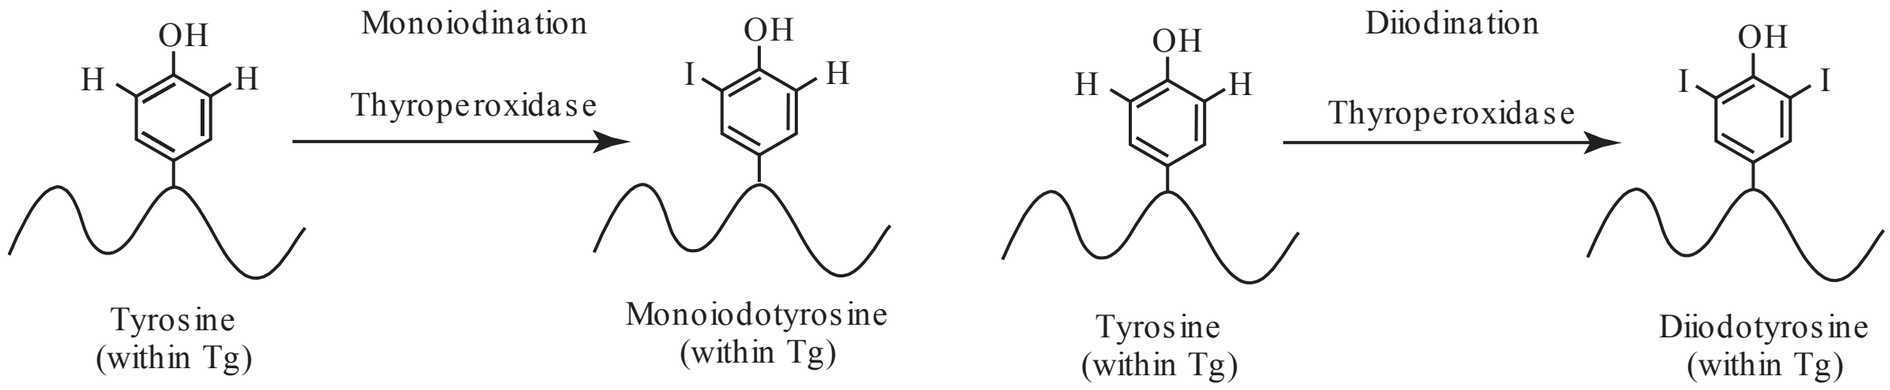

Figure 42-4 Monoiodination and di-iodination of tyrosine.

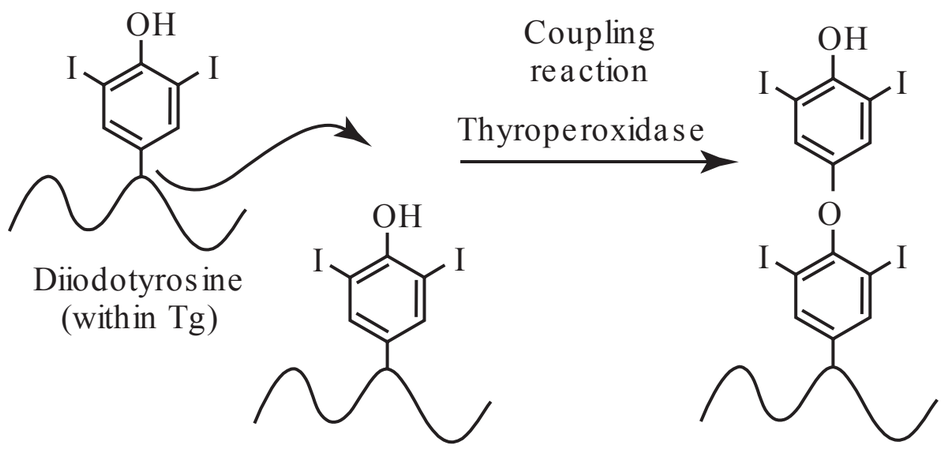

Figure 42-5 Chemical coupling of two molecules of diiodotyrosines (DITs) to produce a molecule of thyroxine (T_4). The reaction is catalyzed by thyroperoxidase (TPO).

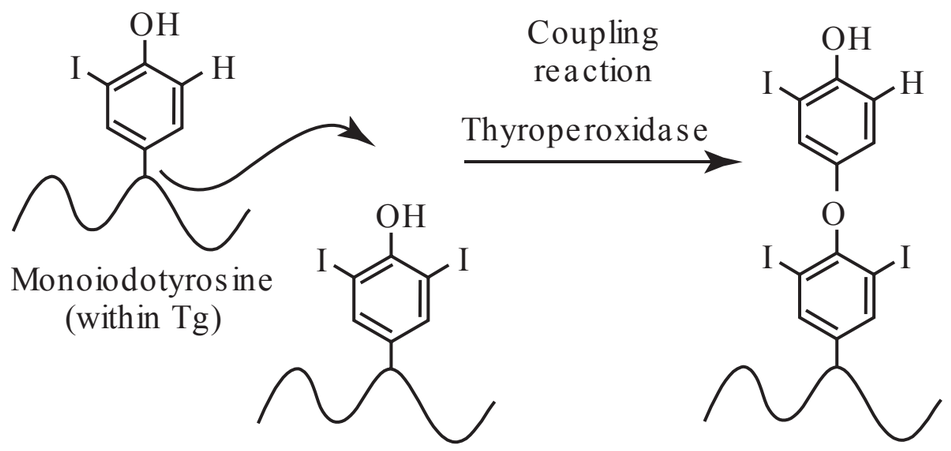

Figure 42-6 Chemical coupling of one molecule of monoiodotyrosine and one molecule of di-iodotyrosine to produce one molecule of T_3. The reaction is catalyzed by thyroperoxidase.

endocytosis; these globules then merge with lysosomes in the follicular cell. Lysosomal proteases break the peptide bonds between iodinated residues of Tg, and MIT, DIT, T_4, and T_3, are released into the cytoplasm of the follicular cell. T_4 and T_3 diffuse into the systemic circulation after their liberation from Tg. DIT and MIT are deiodinated by an intracellular microsomal iodotyrosine dehalogenase (approved gene name iodotyrosine deiodinase, approved symbol IYD; chromosome 6q25.1). The freed iodide is then reused for thyroid hormone synthesis.

Each step in the synthesis of thyroid hormones is regulated by pituitary **thyroid-stimulating hormone (TSH)**. TSH (also known as thyrotropin) stimulates (1) the "iodide pump," (2) Tg synthesis, and (3) colloidal uptake by follicular cells. TSH also regulates the rate of proteolysis of Tg for the liberation of T_4 and T_3. In addition, TSH induces an increase in the size and number of the thyroid follicular cells. Prolonged TSH stimulation leads to increased vascularity and eventual hypertrophic enlargement of the thyroid gland (**goiter**).

Initially, it was believed that both T_4 and T_3 entered cells by passive diffusion across the plasma membrane. However, researchers have now shown that thyroid hormones cross plasma membranes using specific transporters.[15] One important thyroid hormone transporter is monocarboxylate transporter 8 (MCT8; gene symbol SLC16A2; chromosome Xq13.2). MCT10 (SLC16A10; chromosome 6q21-q22) transports iodothyronines and aromatic amino acids across membranes, and MCT10 is likely more preferential than MCT8 in transporting T_3 over T_4 across plasma membranes. Organic anion transporting polypeptide 1C1 (OATP1C1) also has high affinity for thyroid hormone and may be an important component of the transport of T_3 and T_4.

Metabolism

Free (unbound) T_4 (FT_4) is the primary secretory product of the normal thyroid gland. T_4 undergoes peripheral deiodination of the outer ring at the 5′ position to yield T_3. T is deiodination occurs in a number of tissues but primarily in the liver. rT_3, produced by removal of one iodine from the inner ring of T_4, is metabolically inactive and is an end-product of T_4 metabolism. Peripheral deiodination is a rapidly responsive mechanism of control for thyroid hormone balance. Acute or chronic stress or illness causes a shift in the direction of this deiodination, favoring formation of rT_3 rather than T_3. Various medications also shift peripheral deiodination toward the inactive product rT_3.

T_4 and T_3 in the circulation are bound reversibly and almost completely to carrier proteins. These carrier proteins are (1) thyroxine-binding globulin (TBG), (2) thyroxine-binding prealbumin (TBPA; **transthyretin [TTR]**), and (3) albumin. Collectively, these proteins bind 99.97% of T_4 and 99.7% of T_3. Thus only a very small fraction of each of these hormones is unbound and free for biological activity. Because a wide variation exists in the concentration of thyroid hormone binding proteins, even under normal circumstances, a wide variation also exists in total T_4 concentrations among individuals with normal (euthyroid) thyroid function. Total T_3 concentrations also vary with alterations in binding proteins, although usually to a lesser degree than T_4 concentrations. Circumstances in which thyroid hormone-binding protein concentrations are increased or decreased are shown in Box 42-1.

BOX 42-1 Alterations in the Concentration or Affinity of Thyroid Hormone–Binding Proteins

Increases In

A. Thyroxine-binding globulin (TBG) concentration (or affinity)
   1. Genetic (inherited) causes
   2. Nonthyroidal illness (HIV infection, infectious and chronic active hepatitis, estrogen-producing tumors, acute intermittent porphyria)
   3. Normal physiology (pregnancy, newborn)
   4. Drug use (oral contraceptives, estrogens, tamoxifen, methadone)

B. Prealbumin binding (familial euthyroid thyroxine excess)

C. Albumin binding (familial dysalbuminemic hyperthyroxinemia)

D. T_4 binding by autoantibodies (autoimmune thyroid disease, hepatocellular carcinoma)

Decreases In

A. TBG concentration
   1. Genetic (inherited) determination
   2. Nonthyroidal illness (major illness or surgical stress, chronic liver disease, protein-losing enteropathy, nephrotic syndrome)
   3. Drug use (androgens, anabolic steroids, large doses of glucocorticoids)

B. TBG-binding capacity (drugs bound to TBG, such as salicylates and phenytoin)

C. Prealbumin concentration

HIV, Human immunodeficiency virus; T_4, thyroxine; TBG, thyroxine-binding globulin.

Regulation and Control

Thyroid hormone synthesis and secretion are controlled by a negative feedback system (Figure 42-7) involving (1) **thyrotropin-releasing hormone (TRH)** from the hypothalamus, (2) TSH from the pituitary, and (3) thyroid hormones from the follicular cells of the thyroid glands.

Biochemistry

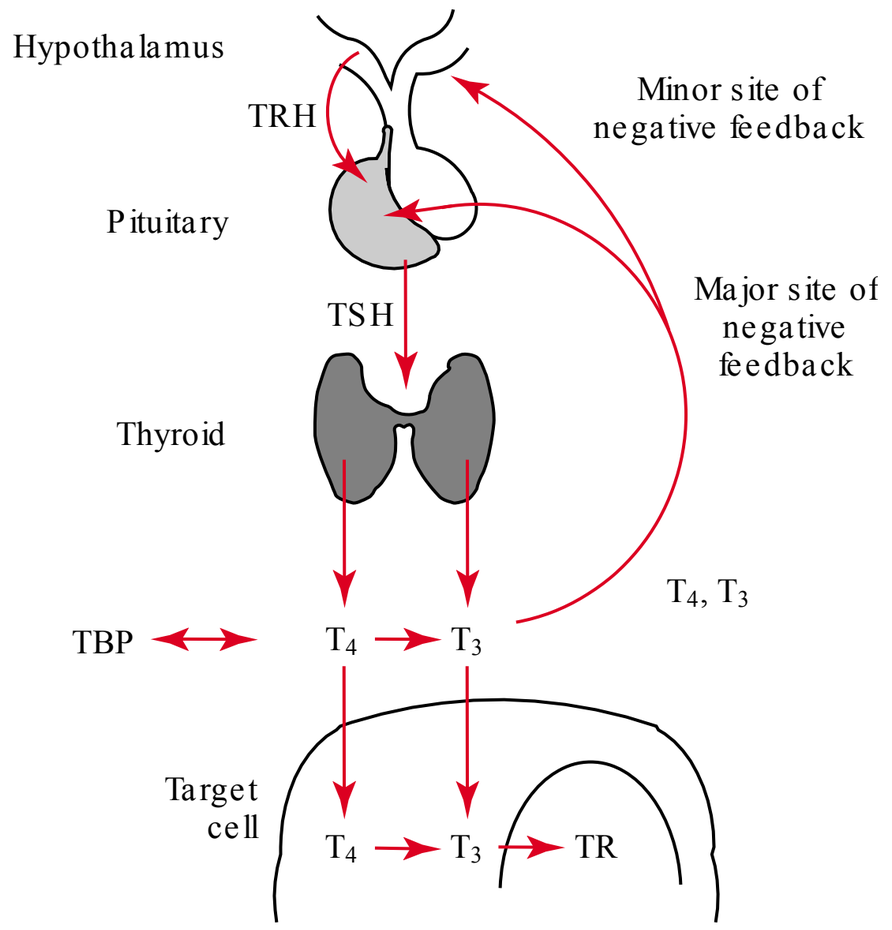
TRH is the modified tripeptide L-pyroglutamyl-L-histidyl-L-prolinamide secreted by the paraventricular nuclei (PVN) in the hypothalamus (Figure 42-8). Its concentrations rise in thyroid hormone deficiency with TRH declining when thyroid hormone is in excess. TRH is delivered to the anterior pituitary gland via the hypothalamic-pituitary portal system. As discussed in Chapter 40, TSH (also known as thyrotropin) is secreted by anterior pituitary cells known as thyrotrophs. In relative terms, TRH has a greater effect on TSH glycosylation than hormone release. However, glycosylation of TSH is necessary for normal TSH bioactivity. When TRH is deficient, TSH may lack potency as the result of insufficient glycosylation, yet nonglycosylated TSH may retain much of its immunoreactivity.

Chemically, TSH is a 30 kDa heterodimeric glycoprotein that shares the 14.7 kDa alpha subunit (gene location: chromosome 6q21.1-q23) with (1) luteinizing hormone (LH), (2) follicular stimulating hormone (FSH), and (3) human chorionic gonadotropin (hCG), whereas each hormone has a unique beta subunit (see Chapters 40 and 44).

Function

The effects of TSH on the thyroid follicular cell are mediated through the TSH receptor. At physiological TSH concentrations, the second messenger system involves G_S proteins, adenylate cyclase and the formation of cyclic AMP. At supraphysiological concentrations (100X normal), TSH signals through the inositol-phosphate diacylglycerol cascade. The 743 amino acid glycosylated thyroid stimulating hormone receptor (TSHR/≈100 kDa) may be in either the "on" conformation, with active signaling, or the "off" conformation, where signaling does not occur. TSH binding to the TSHR places the TSHR in the "on" conformation, leading to stimulation of the thyroid gland.

Within the TSH-stimulated thyroid follicular cell, the (1) activity of the sodium-iodine symporter increases; (2) synthesis of Tg and thyroperoxidase (TPO) increases, and (3) release



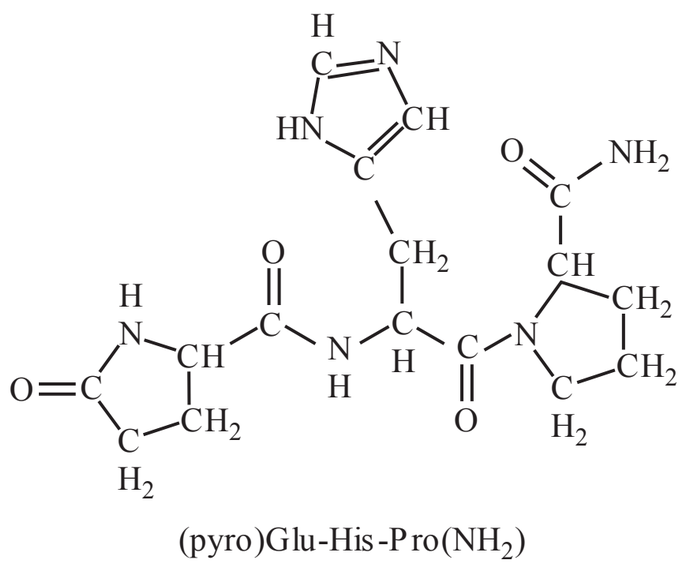


Figure 42-7 Metabolic control of thyroid hormones. Thyrotropin-releasing hormone (TRH) from the hypothalamus enters the hypothalamic-pituitary portal system to release thyroid-stimulating hormone (TSH; thyrotropin) from anterior pituitary thyrotrophs. TSH stimulates the release of thyroxine (T_4) and triiodothyronine (T_3) from the thyroid gland, although most T_3 (□80%) comes from peripheral monodeiodination of T_4 to T_3. More than 99% of T_4 and T_3 is bound to various thyroid hormone–binding proteins. T_4 and T_3 negatively feed back on the hypothalamus and, more powerfully, the pituitary. T_4 and T_3 enter into target tissues, where T_4 is converted to T_3 with T_3 binding to the thyroid hormone receptor (TR).

(pyro)Glu-His-Pro(NH_2)

Figure 42-8 Chemical structure of thyrotropin-releasing hormone (TRH). Note that TRH is a tripeptide (L-pyroglutamyl-L-histidyl-L-prolinamide).

TABLE 42-2 Patterns of Thyroid Dysfunction

	TSH	FT_4	Comments
Primary hypothyroidism	Increased	Decreased	—
Subclinical primary hypothyroidism	Increased	Normal	—
Primary hyperthyroidism	Decreased	Increased	T_3: increased
T_3 toxicosis	Decreased	Normal	T_3: increased
Subclinical primary hyperthyroidism	Decreased	Normal	T_3: normal
Thyroid hormone resistance due to defects in the thyroid hormone receptor	Normal to increased	Increased	T_3: increased; rT_3: increased
Thyroid hormone resistance due to defects in thyroid hormone metabolism of T_4 converted to T_3	Mildly increased	Increased	T_3: decreased; rT_3: increased
Thyroid hormone resistance due to defects in thyroid hormone transport into cells	Normal to increased	Normal to decreased	T_3: increased; rT_3: decreased

of T_4 and T_3 increases. TSH stimulation increases the size and number of thyroid follicular cells.

Thyroid Disorders

Hypothyroidism and hyperthyroidism are the two principal pathological conditions that involve the thyroid gland (Table 42-2). In addition, there are also disorders of the thyroid that are classified as nonthyroidal illnesses (NTIs).

Hypothyroidism[6]

Hypothyroidism is defined as a deficiency in thyroid hormone secretion and action. It is a common disorder that occurs in both mild and severe forms in 2% to 15% of the population. Women are afflicted more often than men, and both sexes are affected more frequently with increasing age. Clinical symptoms and physical signs of hypothyroidism are listed in Box 42-2. **Myxedema** is a severe form of hypothyroidism in which there is accumulation of mucopolysaccharides in the skin and other tissue, leading to a thickening of facial features and a doughy induration of the skin.[1] **Cretinism** is the archaic term used to describe severe hypothyroidism that develops in the newborn period. The appropriate term in this setting is "**congenital hypothyroidism**."

Many structural or functional abnormalities of the thyroid gland lead to thyroid hormone deficiency. Diseases or treatments that directly destroy thyroid tissue or interfere with thyroid hormone biosynthesis frequently cause primary hypothyroidism. The causes of **primary hypothyroidism** are classified as endogenous or exogenous (Box 42-3).[6] Endogenous disorders are conditions that develop within the patient, such as (1) autoimmune thyroid gland dysfunction, (2) inborn errors, and (3) developmental abnormalities. Exogenous disorders are conditions that originate outside the patient, such as (1) iodine deficiency, (2) effects of excess goitrogens, (3) drug effects, and (4) postsurgical hypothyroidism or hypothyroidism following radioactive iodine treatment.

Secondary hypothyroidism occurs as a result of pituitary or hypothalamic disease and/or disorders.

BOX 42-2 Clinical Symptoms and Physical Signs of Hypothyroidism

Clinical Symptoms
- Mental dullness
- Somnolence
- Increased sleeping
- Lethargy
- Easy fatigability
- Hoarseness or deepening of the voice
- Hair loss
- Weight gain
- Cold intolerance
- Menstrual irregularities
- Infertility
- Growth failure
- Delayed puberty in adolescents
- Constipation
- Muscle weakness or cramps
- Depressed affect or frank clinical depression

Physical Signs
- Bradycardia
- Decreased pulse pressure
- Cool and/or dry skin
- Puffy eyes
- Loss of the outer lateral eyebrows
- Delayed relaxation phase of reflexes ("hung-up" reflexes)
- Myopathy
- Carotenemia
- Occasional galactorrhea
- Short stature in affected children
- Radiologic evidence of delayed bone age in children
- Congestive heart failure
- Coma may rarely occur (severe hypothyroidism)

Primary Hypothyroidism

Primary hypothyroidism occurs when the production of T_4 and T_3 is impaired, either because of an extrinsic factor (e.g., iodine deficiency) or because of an intrinsic problem (e.g., **Hashimoto thyroiditis**). As a result, the positive feedback loop causes compensatory thyroid enlargement (goiter)

BOX 42-3 Causes of Primary Hypothyroidism

Endogenous Disorders
Autoimmune thyroid disease (AITD)
- Hashimoto thyroiditis
- Atrophic thyroiditis
- Late-stage Graves disease
- Postpartum thyroiditis

Inborn errors in thyroid hormone biosynthesis (dyshormonogenesis)
- Na^+/Iodide pump dysfunction
- Inadequate organification/iodination—thyroperoxidase (TPO) dysfunction
- Defective thyroglobulin (Tg)
- Deiodinase deficiency
- Pendred syndrome—hypothyroidism and deafness

Developmental disorders involving the thyroid gland
- Congenital hypothyroidism: aplasia, hypoplasia
- Ectopic thyroid: lingual thyroid, thyroglossal duct cyst

Consumptive hypothyroidism (increased metabolism of T_4 and T_3 by tumors)

Exogenous Disorders
Iodine excess/deficiency
Drugs
Thionamides
Lithium
Nitroprusside
Amiodarone
Biologicals (e.g., interferon, interleukin-2)
Dietary goitrogens
Radiation-induced hypothyroidism
Surgical removal of the thyroid gland
Viral or bacterial thyroiditis

through the hypersecretion of TRH and TSH. Hashimoto **thyroiditis** is the most frequent cause of primary hypothyroidism in developed countries where iodine intake is sufficient. Worldwide, iodine deficiency is the most common cause of primary hypothyroidism. T is can result from surgical removal or radioiodine ablation of the thyroid gland in the treatment of **Graves disease**. Primary hypothyroidism is frequently associated with circulating thyroid autoantibodies and may coexist with other diseases (e.g., pernicious anemia) in which autoantibodies are found. In addition, primary hypothyroidism may be one manifestation of autoimmune syndromes of polyglandular endocrine failure.[9]

Reduced concentrations and availability of T_4 and T_3 lead to hypersecretion of pituitary TSH and notable elevations in serum TSH concentrations. T e elevated concentration of TSH is an important laboratory finding, particularly in the early detection of thyroid failure. In subclinical hypothyroidism,[4,9,14] thyroid hormone concentrations remain within the reference interval, but the TSH concentration is persistently elevated. T e etiology of primary hypothyroidism is usually determined through (1) a detailed history, (2) a physical examination, and (3) detection of circulating thyroid autoantibodies, especially those directed againt thyroperoxidase (thyroperoxidase autoantibodies; TPOAb).

Congenital hypothyroidism is caused most commonly by the complete absence of the thyroid gland (athyreosis; thyroid gland agenesis) or partial absence (thyroid gland hypoplasia), and, less commonly, by defects in thyroid hormone biosynthesis or, **central hypothyroidism**. Congenital hypothyroidism occurs once in every 3500 to 4000 live births, and early treatment with thyroid hormone replacement is critical if irreversible neurological damage is to be prevented.[6,10] Screening programs for congenital hypothyroidism have been developed by organizations, such as the (1) American T yroid Association (http://www.thyroid.org, accessed December 04, 2013), (2) National Academy of Clinical Biochemistry (http://www.aacc.org, accessed December 04, 2013), and (3) Royal College of Physicians (http://www.rcplondon.ac.uk, accessed December 04, 2013). North American programs involve total T_4 screening with TSH measurement in the samples with the lowest total T_4 levels (e.g., the bottom 10% of results) whereas European screening programs measure TSH followed by T_4 measurements when TSH values exceed 20 mIU/L. Primary hypothyroidism is readily treatable by the daily administration of oral T_4. During initial treatment, serum FT_4 concentrations adjust quickly, but TSH concentrations remain high. Because the pituitary is slow to register acute changes in thyroid hormone status ("pituitary lag"), 4 to 8 weeks or more may be needed for serum TSH values to reach a new steady state after dose adjustments. Periodic monitoring of serum TSH, one to three times a year, is recommended to help maintain clinical euthyroidism and a serum TSH concentration within the reference interval. Excessive treatment with oral T_4 should be avoided to minimize the risk of accelerated bone resorption and/or atrial fibrillation.

Central Hypothyroidism

In the setting of clinical hypothyroidism with low concentrations of FT_4 and a TSH that is within or below the reference interval or only mildly elevated, central hypothyroidism is diagnosed. Central hypothyroidism is classified as secondary hypothyroidism when there is pituitary disease (with TSH deficiency) versus tertiary (with TRH defieincy) when there is disease of the hypothalamus or the hypothalamic-pituitary portal system.

Causes of central hypothyroidism include (1) a tumor, (2) hemorrhage, (3) trauma, (4) malformation, (5) postinfectious damage, and (6) postsurgical damage. Rare hereditary disorders, such as mutations in the paired-like homeodomain transcription factor-1 (previous name Pit-1; approved gene symbol POU1F1; chromosome 3p11) and PROphet of Pit-1 (gene name PROP paired-like homeobox 1, symbol 1PROP1; chromosome 5q35.3) transcription factors, also have been known to cause hypopituitarism and TSH deficiency. Isolated TSH deficiency is rare, and most patients with secondary hypothyroidism also have other pituitary hormone deficiencies as well (panhypopituitarism).

Other Causes of Hypothyroidism

Other causes of hypothyroidism include (1) autoimmune hypothyroidism, (2) inborn errors in thyroid hormone biosynthesis, (3) iodine deficiency or excess, (4) drug-induced,[13] (5) surgical- and radiation-induced, (6) viral or bacterial thyroiditis, (7) subclinical hypothyroidism,[4,9] and (8) the MCT8 mutation.[11]

Autoimmune Hypothyroidism

Excluding the newborn period, **autoimmune thyroid disease (AITD)** is the most common cause of thyroid disease. Hashimoto thryoiditis (chronic lymphocytic thyroiditis) leads to destruction of the thyroid follicular cells through a cell-mediated autoimmune process. Initially, the gland is usually enlarged. Over time, with destruction of the gland, it will atrophy or become firm or even fibrotic.

Inborn Errors in Thyroid Hormone Biosynthesis

Inborn errors in thyroid hormone biosynthesis (dyshormonogenesis) are rare causes of primary hypothyroidism. T ese defects usually present early in life and will often appear in newborns as large goiters with tracheal compression. Biochemical defects include (1) iodine transport defects from loss-of-function mutations in the sodium iodide symporter (NIS) transporter system, (2) defect in TPO function (DUOX2), and (3) defect in **pendrin** function (a protein that is mutated in Pendred syndrome), (4) Tg deficiency, and (5) iodotyrosine dehalogenase mutations (potentially causing iodine deficiency through loss of MIT, DIT, and iodine in the urine).

Iodine Deficiency or Excess

Worldwide, the most common cause of goiter is iodine deficiency producing "endemic" goiter with or without nodularity. A significant danger of iodine deficiency is maternal hypothyroidism leading to an insufficient supply of thyroid hormone to the fetus in the first half of gestation, when the fetus is entirely dependent on maternal thyroid hormone. Also maternal iodine deficiency will produce fetal iodine deficiency. Excess iodine can cause a transient state of reduced thyroid function.

Drug-Induced[13]

Various drugs effect thyroid function (Table 42-3).

Surgical and Radiation-Induced

Surgical removal of the thyroid gland will produce hypothyroidism. External irradiation of the thyroid gland (e.g., treatment of lymphoma or Hodgkin disease) or ingestion of radioactive iodine also have been known to cause hypothyroidism.

Viral or Bacterial Thyroiditis

Although rarely occurring, some (1) viral infections (such as, subacute thyroiditis or giant cell thyroiditis), or (2) bacterial infections (acute thyroiditis or abscesses)[3] of the thyroid gland will seriously damage the thyroid gland and lead to hypothyroidism.

Subclinical Hypothyroidism[4,9]

Subclinical hypothyroidism is defined by a persistent elevation in TSH (6 to 12 weeks or longer) in the setting of FT_4 concentrations that are repeatedly found within the reference interval.[9] Other conditions in which the concentration of TSH is elevated but the concentration of FT_4 is within the reference interval include (1) recent reinstitution of thyroid hormone replacement therapy, (2) poor compliance with treatment of primary hypothyroidism, (3) recovery from nonthyroidal illness,[1] and (4) interfering heterophilic antibodies in immunoassays falsely raising the TSH.

TABLE 42-3 Effects of Some Drugs on Tests of Thyroid Function

Cause	Drug	Effect
Inhibit TSH secretion	Dopamine L-dopa Glucocorticoids Somatostatin	↓T_4; ↓T_3; ↓TSH
Inhibit thyroid hormone synthesis or release	Iodine Lithium	↓T_4; ↓T_3; ↑TSH
Inhibit conversion of T_4 to T_3	Amiodarone Glucocorticoids Propranolol Propylthiouracil Radiographic contrast agents	↓T_3; ↑rT_3; ↓, □, ↑T_4 and FT_4; □, ↑TSH
Inhibit binding of T_4/T_3 to serum proteins	Salicylates Phenytoin Carbamazepine Furosemide Nonsteroidal antiinflammatory agents Heparin (in vitro effect)	↓T_4; ↓T_3;, □, ↑FT_4; □TSH
Stimulate metabolism of iodothyronines	Phenobarbital Phenytoin Carbamazepine Rifampicin	↓T_4; ↓FT_4; □ TSH
Inhibit absorption of ingested T_4	Aluminum hydroxide Ferrous sulfate Cholestyramine Colestipol Iron sucralfate Soybean preparations Kayexalate	↓T_4; ↓FT_4; ↑TSH

Data from Smallridge RD. Chapter 33, Thyroid function tests. In: Becker KL, ed. Principles and practice of endocrinology and metabolism, 7th edition. Philadelphia, PA: JB Lippincott, 1995:299-306; Stockigt JR. Thyroid hormone changes in critical illness: the sick euthyroid "syndrome." Diagn Endo Metab 1997;15:39-46.

Monocarboxylate Transporter 8 Mutation (Allan-Herndon-Dudley Syndrome)[11]

MCT8 is a protein is encoded by the SLC16A2 gene.[11] MCT8 transports a variety of iodo-thyronines, including the thyroid hormones T_3 and T_4 across cell membranes. A genetic disorder of this gene causes the **Allan-Herndon-Dudley syndrome**. Symptoms of this disorder include (1) normal to slightly elevated concentrations of TSH, (2) elevated concentrations

BOX 42-4 Clinical Symptoms and Physical Signs of Hyperthyroidism

Clinical Symptoms
Nervousness
Erratic behavior
Emotional lability
Restlessness
Sleeplessness
Difficulty concentrating
Smooth and/or shiny hair and/or skin
Weight loss
Excessive sweating
Heat intolerance
Menstrual irregularities
Diarrhea or frequent bowel movements

Physical Signs
Tachycardia
Atrial arrhythmias
Systolic murmurs
Increased pulse pressure
Bounding pulse
Warm and/or damp skin
Softened texture of the skin
Tremor
Increased reflexes
Eyelid retraction
Other signs of ophthalmopathy in Graves disease

BOX 42-5 Causes of Hyperthyroidism

Endogenous Thyroid Disorders
Autoimmune thyroid disease (AITD)
Graves disease
Hashitoxicosis
Postpartum thyroiditis
Gain-of-function mutation in the TSH receptor
Toxic nodule
Toxic multinodular goiter
Toxic adenoma
Familial
Struma ovarii
hCG-induced hyperthyroidism
Gestational transient thyrotoxicosis
TSH receptor sensitivity to hCG
hCG-secreting tumors
Secondary hyperthyroidism (e.g., central hyperthyroidism)

Exogenous Disorders
Thyroid destruction from viral or bacterial thyroiditis
Iodine-induced hyperthyroidism
Thyroid hormone ingestion (thyrotoxicosis factitia)

of T_3, (3) reduced concentrations of T_4, (4) developmental delay and (5) mobility problems.

Hyperthyroidism[17]

Hyperthyroidism is defined as a hypermetabolic condition caused by excessive production of thyroid hormones. This disorder is caused by a number of conditions resulting from excess availability of thyroid hormones. Some clinicians prefer the general term **thyrotoxicosis** rather than hyperthyroidism to define the hypermetabolic state associated with increased amounts of thyroid hormone in the circulation. Clinical symptoms and physical signs of hypothyroidism are listed in Box 42-4. The causes of hyperthyroidism are listed in Box 42-5. Endogenous disorders causing hyperthyroidism include (1) intrinsic thyroid disease (primary hyperthyroidism), (2) ectopic thyroid tissue (struma ovarii), and (3) disorders of the hypothalamus or pituitary causing excess TSH secretion (central hyperthyroidism). Exogenous causes of hyperthyroidism (disease related to external factors) include (1) infectious origins (thyroid gland inflammation and destruction), (2) iodine-induced hyperthyroidism, and (3) thyroid hormone ingestion (thyrotoxicosis factitia). In North America, the most common cause of hyperthyroidism is Graves disease, an autoimmune disorder that affects 0.4% of the US population.[5]

Women are more prone to developing hyperthyroidism than men. The ratio of females to males with Graves disease is approximately 5:1. Hyperthyroidism is often easier to diagnose by clinical observation than is hypothyroidism. In some patients with hyperthyroidism, particularly individuals older than 60 years of age, the diagnosis may not be self-evident, and symptoms may be dismissed or attributed to stress or other causes.[16] This is conditions is termed "**apathetic hyperthyroidism**."

The biochemical picture of primary hyperthyroidism shows increases in concentrations of T_4 and T_3 with the quantities of TSH suppressed to undetectable concentrations (or less than 0.01 mU/L). Secondary hyperthyroidism is hyperthyroidism resulting from excess TSH. Such cases include TSH-secreting pituitary adenomas and pituitary resistance to thyroid hormone with normal peripheral sensitivity.

When testing for primary hyperthyroidism, the concentration of TSH is suppressed and the serum FT_4 concentration should be determined which will typically be elevated. Finding a low TSH concentration and an elevated FT_4 concentration is usually sufficient to establish the diagnosis of hyperthyroidism in the setting of compatible symptoms. If the TSH concentration is low but the FT_4 concentration is within the reference interval, a T_3 measurement should be performed, because serum T_3 concentrations are often elevated to a greater degree than T_4 in the early phases of Graves disease and in some patients with solitary or multinodular toxic goiters (so-called **T_3 thyrotoxicosis**). A persistently suppressed concentration of serum TSH with normal concentrations of serum T_3 and FT_4 define **subclinical hyperthyroidism** (assuming conditions that suppress TSH are excluded such as the use of high dose glucocorticoids or dopamine), which is a defined biochemical entity with few or subtle clinical symptoms. Although the measurement of the free portion of T_3 (FT_3) is helpful to compensate for variations in binding proteins, measurements of total T_3 are usually sufficient because T_3 should be measured only in cases of suspected hyperthyroidism. FT_3 assays are more expensive that total T_3 measurements and total T_3 assays

are more robust than FT_3 assays. A number of medications and acute and chronic illnesses do cause a transient lowering of T_3 concentrations. In patients with NTIs,[1] an early diagnosis of hyperthyroidism may not be possible until the other illness has resolved.

Occasionally, increases in serum concentrations of T_4 and T_3 will occur (1) as a result of the ingestion of large quantities of exogenous thyroid hormones, or (2) due to the release of thyroid hormones as a result of damage to the thyroid parenchyma associated with subacute thyroiditis or chronic lymphocytic thyroiditis. The increase in T_4 and T_3 concentrations may be associated with clinical findings compatible with hyperthyroidism. This diagnostic dilemma, however, is resolved by performing a radioactive iodine uptake test and finding a low radioactive iodine uptake (percent of orally administered radioactive iodine taken up by the gland at 6 or 24 hours) in cases where thyroid damage is releasing excessive thyroid hormone. When this occurs in people with preexisting Hashimoto thyroiditis, the term "**hashitoxicosis**" can be applied. In most cases of thyroiditis with hyperthyroidism, the condition is self-limited and will resolve without residual thyroid function abnormalities. Certainly thioureas are not indicated therapeutically; beta-blockers such as propranolol can be used to diminish symptoms.

Treatments

Treatments for hyperthyroidism include (1) administration of antithyroid drugs, (2) radioiodine ablation, and (3) surgical removal of the thyroid gland. Treatment is typically designed to decrease thyroid hormone production or inhibit peripheral conversion of T_4 to T_3. At the time treatment is initiated, measurements of serum FT_4 concentrations are recommended every few weeks until symptoms abate and serum values normalize. Continuous monitoring for recurrence of hyperthyroidism is suggested two or three times a year after successful therapy. Because the pituitary gland is suppressed in hyperthyroidism, measurement of the concentration of serum TSH is not a good monitor of thyroid status in the immediate period following the start of antithyroid therapy. In fact, TSH concentrations remain suppressed for months after the patient becomes clinically euthyroid. Ablation of thyroid tissue or overtreatment with antithyroid drugs sometimes leads to clinical hypothyroidism and an increase in serum TSH. Surveillance for hypothyroidism in previously treated hyperthyroid patients must continue for the life of the patient and is best monitored with a serum TSH measurement.

Specifc Causes of Hyperthyroidism

Specific causes of hyperthyroidism include (1) Graves disease,[5] (2) Hashimoto thyroiditis and postpartum thyroiditis, (3) toxic nodular or multinodular goiter, (4) gain-of-function mutations in the TSH receptor, (5) central hyperthyroidism, (6) hyperthyroidism due to human chorionic gonadotropin, (7) iodine-induced, and (8) other exogenous causes of hyperthyroidism. It should be noted that T_3 toxicosis is not a specific diagnosis. T_3 toxicosis is a descriptive term for cases where clinical hyperthyroidism is observed in the setting of a suppressed TSH, normal FT_4 and elevated T_3. T_3 toxicosis can represent an early phase in hyperthyroidism or the case of hyperthyroidism occurring in the setting of iodine deficiency (see Table 42-2).

Thyroid storm (also known as thyrotoxic crisis) is an uncommon syndrome of severe and accelerating hyperthyroidism potentially manifested in (1) tachycardia, (2) restlessness, (3) high-output congestive heart failure, (4) fever greater than 41 °C (106 °F), (5) extreme irritability, (6) delirium or coma, (7) hypotension, and (8) vomiting or diarrhea. In older individuals, an unusual variant of hyperthyroidism is termed apathetic hyperthyroidism.[16] These disorders are descriptive terms and do not convey the cause of the underlying hyperthyroidism.

Likewise subclinical hyperthyroidism is not a specific etiology but the description of a clinical and biochemical variant of hyperthyroidism. A persistent depression in the concentration of TSH when FT_4 and T_3 concentrations are normal identifies subclinical hyperthyroidism. Patients with it have increased frequencies of atrial fibrillation and osteoporosis. In the absence of a clinically compatible cardiac arrhythmia or significantly reduced bone mineral density, there is little justification for the use of antithyroid drugs.

Graves Disease[5]

Graves disease is an autoimmune disease where the thyroid is overactive, producing an excessive amount of thyroid hormone. It affects approximately 0.4% of the US population and results from agonistic autoantibodies that bind to, and activate, the TSH receptor, producing hyperthyroidism. Similar to Hashimoto thyroditis, genetic susceptibility to Graves disease is polygenic. It is associated with HLA-DR3, a MHC class II cell surface receptor encoded by the human leukocyte antigen complex on chromosome 6 region 6p21.31. Other genes that influence susceptibility to AITD encode CTLA-4, PTPN22, FOXP3, CD25, CD40, thyroglobulin and the TSH receptor.

The classical clinical triad described in patients with Graves disease consists of (1) goiter and biochemical hyperthyroidism, (2) exophthalmos, and (3) nonpitting pretibial myxedema, although the latter is rarely seen.

Thyroperoxidase autoantibodies (TPOA) and Tg autoantibodies (TgA) antibodies are found in the sera of patients with both Hashimoto thyroiditis and Graves disease. However, these autoantibodies do not distinguish the two conditions. TSH receptor autoantibody (TRA) testing is available for stimulatory autoantibodies (TSIs) and receptor-binding autoantibodies (thyrotropin-binding inhibitory immunoglobulins [TBIIs]). TSI and TBII positivity is common in Graves disease and uncommon in Hashimoto thyroiditis.

Hashimoto Thyroiditis and Postpartum Thyroiditis

Hashimoto dthyroiditis (also known as Hashimoto disease and chronic lymphocytic thyroiditis) is an autoimmune disease in which the thyroid gland is attacked by a cell-mediated autoimmune processes. During the clinical course of Hashimoto

thyroiditis, if a period of accelerated destruction occurs, subsequent release of thyroid hormone will produce a transient hyperthyroidism, termed hashitoxicosis (hyperthyroidism in patients with Hashimoto thyroiditis). Hashitoxicosis needs to be differentiated from Graves disease, because the treatments for these two conditions are different. Hashitoxicosis is self-limited, and if any treatment is required, β-blockers (such as, propranolol) are used to suppress the effects of excess catecholamines (such as, tachycardia). Patients with postpartum thyroiditis may experience a period of transient, usually self-limited, hyperthyroidism from accelerated breakdown of thyroid tissue. Alternatively postpartum thyroiditis can cause primary hypothyroidism or, sequential hyperthyroidism and then hypothyroidism or the reverse order of hypothyroidism and then hyperthyroidism. After 1 year, most women with postpartum thyroiditis enter into the euthyroid state but are at increased risk for the development of hypothyroidism later in life. Subacute (viral) or acute (bacterial) thyroiditis has also been known to produce transient hyperthyroidism.

Toxic Nodular or Multinodular Goiter

A subset of patients with nodular or multinodular goiter develop hyperthyroidism. When hyperthyroidism is caused by these lesions, the term toxic has been used (**toxic multinodular goiter**). In the older literature, toxic multinodular goiter is referred to as Plummer disease.

Gain-of-Function Mutations in the Thyroid-Stimulating Hormone Receptor

A rare familial, autosomal dominant hyperthyroidism has been known to result from gain-of-function mutations in the TSH receptor. Certain heterozygous mutations have caused infantile hyperthyroidism, whereas in infants homozygous for such mutations, potentially severe neonatal thyrotoxicosis has been observed requiring emergency thyroidectomy.

Central Hyperthyroidism

Although rare, TSH-secreting anterior pituitary adenomas have been observed. Their diagnosis is suggested by (1) clinical hyperthyroidism, (2) elevated concentrations of FT_4, (3) normal to elevated TSH concentration, and (4) evidence of a pituitary mass on a computed tomography (CT) scan or via magnetic resonance imaging (MRI).

Hyperthyroidism Due to Human Chorionic Gonadotropin

hCG–induced hyperthyroidism is observed in (1) gestational transient thyrotoxicosis, (2) TSH receptor hypersensitivity to appropriate hCG concentrations during pregnancy, and (3) hCG-secreting tumors. In gestational transient thyrotoxicosis, (1) testing for thyroid autoantibodies is negative, (2) hyperthyroidism is typically clinically mild, and (3) treatment is not usually required.[19] There is one case report of a daughter and her mother who both developed hyperthyroidism during pregnancy that were shown to express a mutant TSH receptor with increased sensitivity to normal pregnancy-levels of hCG. Tumors that secrete hCG, such as (1) choriocarcinoma, (2) hydatidiform mole, or (3) metastatic embryonal carcinoma have been known to cause hyperthyroidism.

Iodine-Induced Hyperthyroidism

In a patient with iodine deficiency and underlying Graves disease, or nodular or multinodular goiter, iodine administration may lead to hyperthyroidism. Before iodine replenishment is provided, hyperthyroidism is likely kept in check by iodine deficiency. The phenomenon of iodine-induced hyperthyroidism is termed the Jod-Basedow syndrome (or phenomenon).

Other Exogenous Causes of Hyperthyroidism

Thyroid gland destruction from any cause may release excessive amounts of thyroid hormones. Intentional or unintentional ingestion of excess thyroid hormone will also produce hyperthyroidism.

When thyroid hormone is ingested or released from an inflamed or damaged thyroid gland, subsequent suppression of TSH reduces thyroidal iodine uptake, which is reflected in a reduction in the radioactive iodine uptake test. Likewise, glandular suppression or destruction lowers circulating Tg concentrations. If T_3 is ingested, hyperthyroidism may develop, producing an unusual set of biochemical abnormalities including (1) suppressed concentrations of TSH, (2) suppressed concentrations of FT_4 and total T_4, and (3) elevated total T_3 and FT_3.

Nonthyroidal Illness (Sick Euthyroid Syndrome)[8]

Many disorders are associated with variation in the concentration of thyroid hormones in the absence of definable thyroid disease (Table 42-4). For example, disorders resulting from (1) significant nutritional deprivation, (2) acute severe illness, or (3) chronic illness often result in changes in thyroid function. Collectively they are characterized as nonthyroidal illnesses (NTI; **sick euthyroid syndrome**).

A progressive spectrum of thyroid test result anomalies often accompany non-thyroidal illnesses in euthyroid patients. The earliest and most common changes that occur are a reduction in the serum concentrations of total and free T_3, sometimes to extremely low concentrations, and an elevation in the serum concentration of rT_3 (the "low T_3 state"). These changes have been ascribed to a block in the 5′ deiodinases that convert T_4 to T_3 in peripheral tissue. This conversion is inhibited in

TABLE 42-4 Nonthyroidal Illness[1]

Hormone	Initial	Midcourse	Prolonged	Resolution
TSH	Normal	Normal to decreased	Decreased	Increases
T_4	Normal	Normal to decreased	Decreased	Increases
T_3	Decreased (−)	Decreased (− −)	Decreased (− − −)	Increases
rT_3	Increased (+)	Increased (+ +)	Increased (+)	Decreases

Note: The severity of decreased T_3 is proportional to the number of (−) signs. The degree of increase in rT_3 is proportional to the number of (+) signs.
T_3, Triiodothyronine; rT_3, reverse T_3; T_4, thyroxine; TSH, thyroid-stimulating hormone.

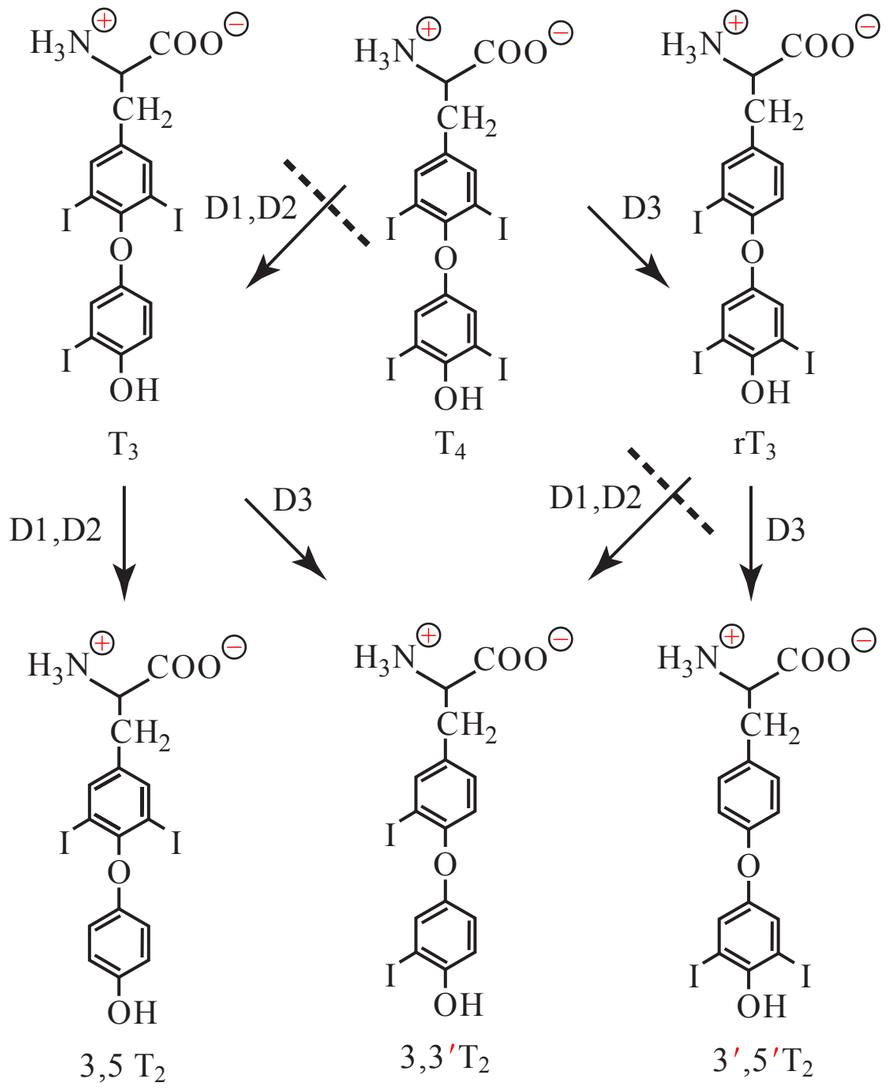

Figure 42-9 Effects of altered deiodination. In states of nonthyroidal illness (e.g., the sick euthyroid syndrome), thyroid hormone deiodination patterns are altered with reduced T_3 concentrations and elevated concentrations of rT_3.

patients with (1) acute and chronic nutritional problems, (2) poorly controlled diabetes mellitus, and (3) use of drugs such as hydrocortisone and beta blockers.

Serum TSH concentrations are usually normal in euthyroid sick patients, but may be mildly to moderately depressed with moderate to severe NTI or slightly elevated during recovery from a severe illness (Figure 42-9).[2] Causes of these transient abnormal TSH concentrations are not fully understood, but may relate to the effects of endogenous or exogenous hormones, such as glucocorticoids or dopamine, which independently suppress secretion of pituitary TSH concentrations. Other possible causes include altered nutrition or altered biological activity of immunoreactive TSH.[8] Decreased T_4 levels may result from T_4 displacement from thyroid hormone binding proteins.

As patients recover from NTIs, many of the thyroid test abnormalities revert to normal. T_4 concentrations will be corrected first followed by a rise in the concentration of T_3. Serum TSH may also transiently rebound to high concentrations for several days or weeks before returning to normal.

Thyroid Hormone Resistance

Loss-of-function mutations in the TRβ chain, or less commonly, the TRα chain, lead to two distinct and rare syndromes of thyroid hormone resistance.[2] In the autosomal dominant TRβ chain mutations, supraphysiologic concentrations of T_3 and T_4 (and FT_3 and FT_4) are required to maintain the euthyroid state. Therefore, in the absence of clinical hyperthyroidism, if the concentrations of T_4, FT_4, T_3, and FT_3 are elevated with a TSH in the upper reference interval or mildly elevated, thyroid hormone resistance is likely. Sometimes thyroid glandular enlargement is seen. Some affected patients may even have mild clinical findings of hypothyroidism. Inappropriate treatment of thyroid hormone resistance with antithyroid drugs has been known to induce hypothyroidism.

Euthyroid Hyperthyroxinemia

Euthyroid hyperthyroxinemia exists when the total T_4 concentration is elevated, yet the patient is clinically euthyroid. Because FT_4 measurements have supplanted total T_4 measurements, this disorder is not commonly encountered in modern clinical practice.

Besides TBG elevations and the thyroid hormone resistance syndromes, euthyroid hyperthyroxinemia also result from acute illness (though the mechanism is not well understood) or autosomal dominant abnormalities in albumin (familial dysalbuminemic hyperthyroxinemia) or transthyretin (familial euthyroid thyroxine excess). In these two disorders, the concentrations of TSH, FT_4 and T_3 are within their reference intervals, whereas the concentration of total T_4 is elevated (see Table 42-4).

Analytical Methodology

In clinical practice, thyroid function tests are routinely measured to diagnose disorders of the thyroid[3,7] (see Table 42-1). For example, in combination with information obtained from a (1) a history, (2) a physical, and (3) laboratory results; patients are classified as (1) hypothyroid, (2) hyperthyroid, or (3) euthyroid (Figure 42-10).

Almost all laboratory tests for thyroid function are commercially available in either kit form or on automated immunoassay instruments. The following is a brief description of tests that are used for the evaluation of thyroid status. Package inserts that accompany commercial products also are a source of additional information. Reference intervals for the analytes discussed later are found in Table 50-1 in Chapter 50.

Measurement of Thyroid-Stimulating Hormone

Immunoassay is the method of choice for the measurement of serum TSH in the clinical laboratory. Human TSH is a 28 to 30 kDa dimeric glycoprotein consisting of a 92 amino acid alpha subunit (identical to the alpha subunit of hCG, follicle-stimulating hormone, and LH) and a 112 to 118 amino acid beta subunit. Current generation TSH assays distinguish mild to modest TSH suppression (due to, for example, overtreatment of hypothyroidism) from severely suppressed TSH levels as observed in Graves disease.

Principles of Thyroid-Stimulating Hormone Immunoassays

Essentially all current TSH methods used in clinical laboratories are two-site "sandwich" heterogeneous immunoassays involving (1) enzyme, (2) fluorometric substrate, or (3) chemiluminescent labels. These assays employ two antibodies with

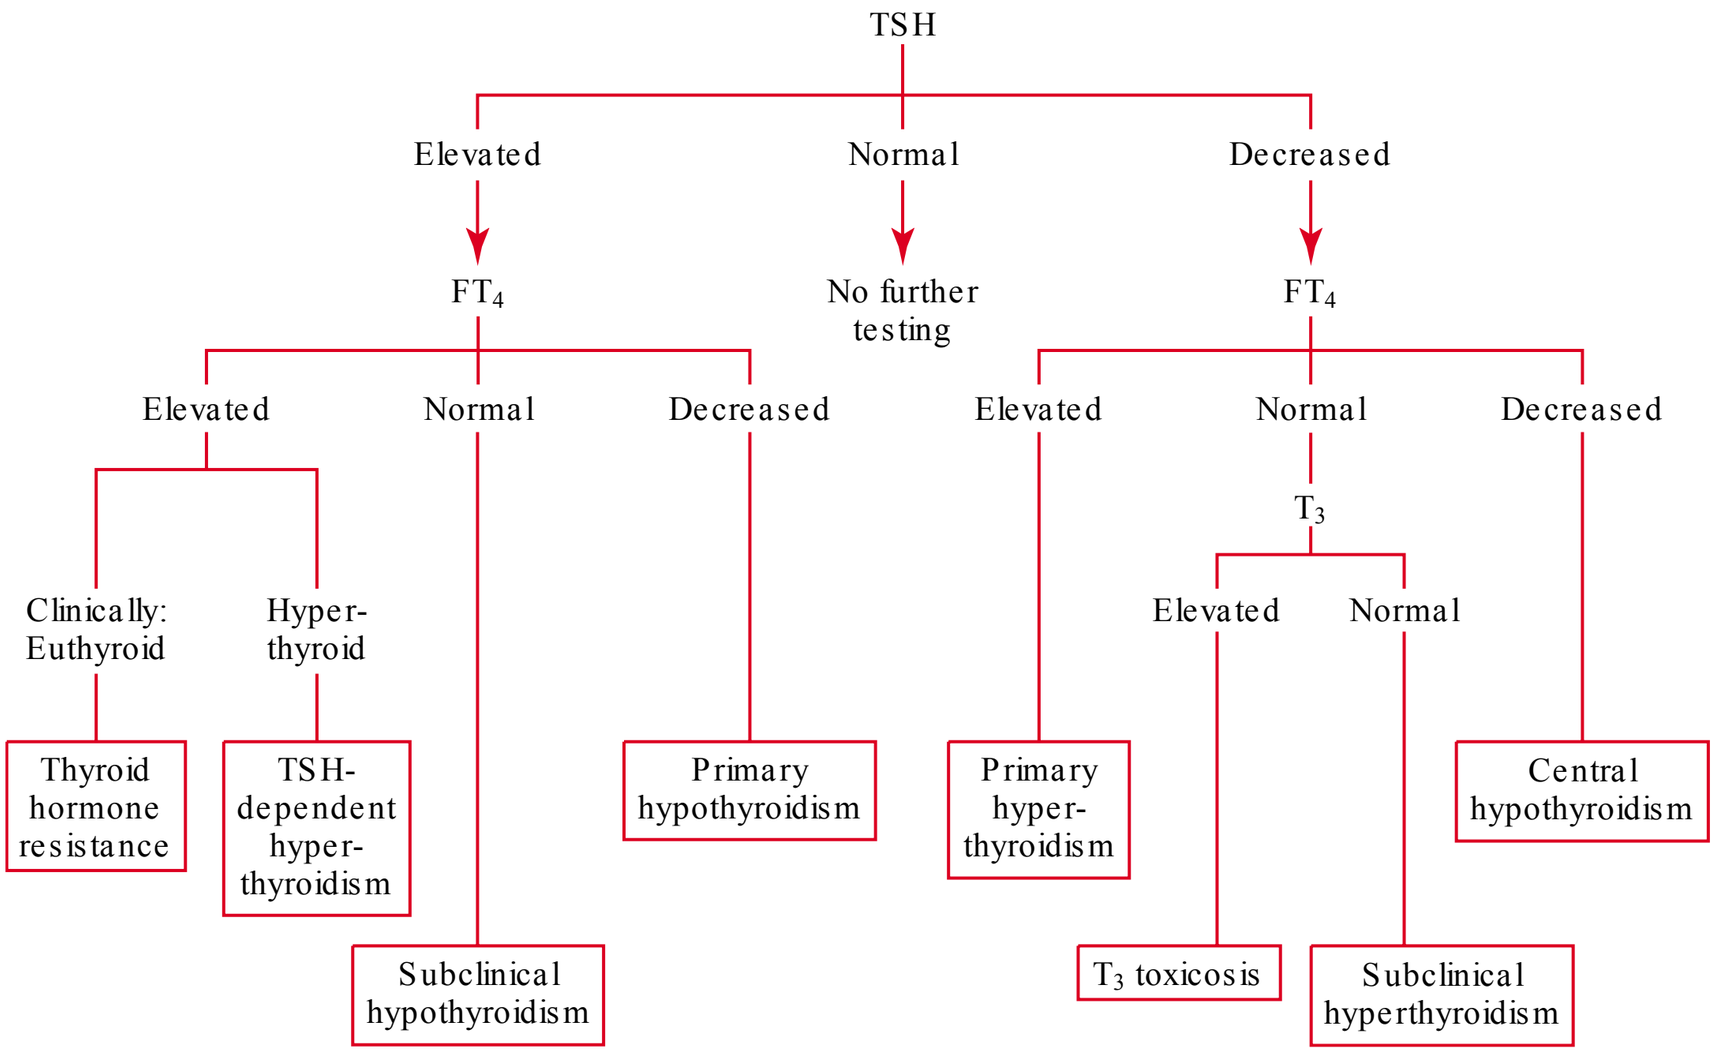

Figure 42-10 Suggested algorithm for the laboratory evaluation of thyroid function.

the capture antibody directed toward the alpha subunit and a signal antibody that recognizes an epitope on the unique beta subunit. Heterogeneous immunoassays differ in the method used to separate bound and free fractions before application of the signal antibody. In contrast to the inverse dose-response relationship in radioimmunoassay (RIA), immunometric assays generate a proportional dose-response calibration curve with higher signals corresponding to increased concentrations of analyte. Because the physiological interval of TSH concentrations is typically less than three orders of magnitude, high-dose hook effects are rarely encountered with TSH immunoassays. When compared with traditional competitive immunoassays, such as RIA, heterogeneous immunoassays for TSH offer (1) lower limits of detection, (2) rapid turnaround time, and (3) a wider linear measurement range.

Specimen Collection and Storage

Both serum and plasma are used for TSH measurements. TSH is stable for 5 days at 2 to 8 °C, and for at least 1 month when stored frozen. For newborn screening, whole blood may be collected by heel puncture 48 to 72 hours after birth.

Comments on Thyroid-Stimulating Hormone Measurements

Secretion of TSH is circadian with peak concentrations of TSH occurring between 0200 and 0400, and the lowest between 1700 and 1800. Low-amplitude oscillations occur throughout the day. TSH surges immediately after birth, reaching a peak of 25 to 160 mIU/L within 30 minutes and declining back to cord blood concentrations by postpartum day 3. TSH concentrations stabilize to near adult concentrations within the first few weeks of life. In the first trimester of pregnancy, TSH concentrations decline as hCG stimulates the maternal thyroid gland to produce thyroid hormone, sometimes leading to a TSH concentration that is just below the lower limit of the reference interval. Reference intervals for adult TSH concentrations are the same for men and women (generally near 0.4 to 4.5 mIU/L). However, there is active discussion that the upper limit of the reference interval may be as low as 2.5 to 3.5 mIU/L if people with thyroid autoantibodies and/or abnormal thyroid ultrasound findings are excluded from the reference population.

Measurement of Total Thyroxine

T_4 is the principal hormone secreted by the thyroid, and its circulating concentration is under the control of TSH. T e hormone is synthesized from tyrosine residues on Tg in the colloid of the thyroid gland. Circulating T_4 is highly (>99.9%) protein bound, and the fraction that is bound to protein is biologically inactive.

Methodology

Immunoassays and instrument-based methods are used to measure T_4 in biological fluids, predominantly serum or plasma.

Immunoassays

Many clinical laboratories measure total T_4 by using an automated competitive immunoassay. Most of these T_4 immunoassays use high-affinity polyclonal antibodies produced against an albumin-T_4 conjugate. T ese polyclonal antibodies are highly specific and display minimal cross-reactivity with T_3. Tg sometimes has been used as the immunogen, because it contains iodinated tyrosine residues that are the precursors of T_4 and T_3. Monoclonal antibodies against T_4 have also been developed.

Immunoassays of total T_4 measure both free and protein-bound hormone. Accurate measurement of total T_4 therefore requires dissociation of the hormone from serum proteins, such as (1) TBG, (2) albumin, and (3) transthyretin, that bind more than 99.9% of circulating T_4. Various blocking agents have been used to dissociate T_4 from TBG. The most common of these blocking agents is (1) 8-anilino-1-naphthalene-sulfonic acid (ANS), although (2) salicylate, (3) thimerosal, and (4) phenytoin have also been used for this purpose. Barbital is used to dissociate T_4 from transthyretin.

Considerable effort has been directed toward the development of immunoassays that do not require the use and measurement of radioactivity, and nonisotopic assays for T_4 are widely available for use on various automated immunoassay systems, or adaptable to automated chemistry platforms. Chemiluminescent and electrochemiluminescent assays have also been adapted for use on automated platforms.

Instrument-Based Methods

Instruments used to measure T_4 in human serum include (1) electron capture gas chromatography, (2) high-performance liquid chromatography, and (3) isotope dilution tandem mass spectrometry. The latter method has been suggested as a reference method for assay of T_4. With this technique, (1) tritium-labeled T_4 is added as an internal standard followed by (2) extraction, (3) derivatization, and (4) quantitation by combined gas chromatography–mass spectrometry.

Specimen Collection and Storage

Serum is the preferred specimen for the measurement of T_4, but plasma with ethylenediaminetetraacetic acid (EDTA) or heparin as anticoagulant has also been used. If plasma is used, repeated freeze-thaw cycles should be avoided as fibrin clots may form producing potentially spurious results due to changes in specimen viscosity. Gel barrier collection devices do not have any apparent adverse effect on T_4 methods. T_4 is a stable analyte with no appreciable change in concentration for up to 7 days at room temperature, or 30 days when frozen. Mild to moderate hemolysis and lipemia do not significantly affect most T_4 immunoassays; however, grossly hemolyzed specimens should be avoided because of dilutional effects. T_4 autoantibodies interfere with some immunoassays and may produce erroneously low or high results, depending on the method. Such interferences should be considered when there is discordance between the clinical and laboratory findings.

Heel stick capillary specimens have been used for T_4 measurement, as have dried blood specimens collected on filter paper. Dried blood specimens are stable and easily transported and are widely used in the US to screen neonates for congenital hypothyroidism. T_4 is extracted from a punched out disk of blood saturated filter paper into a buffer before assay. The filter paper should not be exposed to extreme heat or light.

Comments on Total Thyroxine Measurements

Because it reflects mostly inactive (protein-bound) hormone, the quantity of total T_4 alone provides limited clinical information. For this reason, FT_4 measurements are preferred over total T_4 measurements for routine testing.

Cord blood T_4 concentrations are lower in preterm than in full-term neonates, and they correlate positively with birth weight in full-term infants. At birth, serum total T_4 concentrations are higher in neonates because of the maternal estrogen-induced increase in serum TBG; FT_4 concentrations are near adult concentrations. The concentration of total T_4 rises abruptly in the first few hours after birth and declines gradually until adolescence.

Measurement of Triiodothyronine

T_3 is the principal active thyroid hormone with approximately 20% of circulating T_3 secreted by the thyroid gland, and the remainder is produced by deiodination of T_4 in the peripheral tissues. Like T_4, T_3 is highly bound to protein with less than 1% of the total concentration as free active hormone. Compared with T_4, however, it is less tightly bound to serum proteins by about an order of magnitude. Consequently, the displacement of bound T_3 from proteins is essentially complete in the presence of conventional blocking agents, such as ANS. Also T_3 does not ordinarily displace T_4 from thyroid hormone–binding proteins.

Methods

Immunoassays are the techniques of choice to measure T_3 in body fluids, predominantly serum or plasma.

Radioimmunoassays

Numerous commercial RIA kits are available for measuring total T_3 concentrations in serum. Most analytical designs use a ^{125}I-T_3 tracer and incorporate antibodies bound to a solid phase, such as the wall of a cuvette or paramagnetic particles.

Nonisotopic Immunoassays

Nonisotopic immunoassays for T_3 are similar to total T_4 methods. Many of the T_3 methods have been developed for use on automated immunoassay systems, and some are compatible with chemistry platforms. Many commercial methods use enzyme labels, such as peroxidase or alkaline phosphatase, conjugated to T_3 or anti-T_3 antibodies. Enzyme activity is determined by using a variety of sensitive (1) photometric, (2) fluorescent, or (3) chemiluminescent substrates. Automated platforms that employ chemiluminescent labels are the analytical systems of choice to measure T_3. Both heterogeneous and homogeneous immunoassays for T_3 have been described.

Specimen Collection and Storage

Serum is the preferred specimen, but plasma with EDTA or heparin as anticoagulant may be used. Serum specimens should be tested within 24 hours of collection, or stored at 2 °C to 8 °C if tested beyond 24 hours. Frozen specimens are stable for at least 30 days. Turbid samples may require centrifugation before testing.

Comments on Total Triiodothyronine Measurements

Significant discrepancies have been observed when the results of different T_3 immunoassays were compared using reference

sera. Interlaboratory quality assurance (proficiency testing) results also demonstrate higher analytical variance for T_3 compared with T_4 methods. Among the factors that have been suggested to account for the poorer analytical performance of T_3 immunoassays are the (1) lower concentration of T_3 in serum, (2) greater antibody cross-reactivity, (3) protein interferences, and (4) different limits of detection for T_3 methods. Total T_3 measurements are useful in the diagnosis and monitoring of hyperthyroid patients with suppressed TSH and normal FT_4 concentrations ("T_3-thyrotoxicosis"); T_3 measurements have only limited value in euthyroid and hypothyroid patients. Thyroid hormone replacement in hypothyroid patients is monitored by TSH and FT_4 measurements and is not monitored by measuring T_3.

Measurement of Reverse Triiodothyronine

Several RIA methods for measuring rT_3 have been developed and commercial assays are available. However, none of these assays have been adapted to automated platform because rT_3 measurement has limited diagnostic value. The diagnosis of NTI can usually be established without measuring rT3.

Measurement of Free Thyroid Hormones

Numerous methods have been developed for assessing the concentrations of FT_4 and FT_3 in serum. These methods include (1) direct assays that currently serve as reference methods and (2) indirect or estimate assays that are more widely available for general laboratory use.

Direct Reference Methods

Direct measurement of FT_4 (and FT_3) in serum is a technical challenge as the quantity of free hormone in normal serum is exceedingly low—typically less than 100 pmol/L (7.8 ng/dL). Reliable methods for measuring FT_4 and FT_3 in serum include those that separate free and bound hormone fractions by (1) direct equilibrium dialysis or (2) ultrafiltration. After separation, the free concentration is measured by a sensitive analytical method, such as immunoassay or mass spectrometry.

Direct Equilibrium Dialysis

In this procedure isotopically labeled T_4 or T_3 "tracer" is added to the specimen before dialysis is performed. When equilibrium is established, concentrations of the tracer on both sides of the dialysis membrane are used to calculate the ratio of bound to free hormone, so the FT_4 (or FT_3) concentration is able to be calculated based on the total T_4 or T_3 concentration. If the amount of tracer added to the specimen is small in comparison with the endogenous hormone concentration, minimal disruption of free/bound hormone is noted.

Ultrafiltration

The ultrafiltration procedure for FT_4 determination in serum is significantly less time-consuming than dialysis. In this method, the serum specimen is (1) adjusted to a pH of 7.4, (2) incubated for 20 minutes at 37 °C (to achieve equilibrium of the binding at this temperature), and then (3) applied to an ultrafiltration device for centrifugation for 30 minutes at 37 °C and 2000 × g (using a fixed-angle rotor). Subsequently the ultrafiltrate is analyzed for T_4 by immunoassay.

Comments

FT_4 assays based on ultrafiltration measure free hormone without the need for total hormone measurements. Direct equilibrium dialysis and ultrafiltration methods are unaffected by either variations in serum binding proteins or thyroid hormone autoantibodies. Mean values obtained in euthyroid healthy subjects are reported to be slightly higher when using ultrafiltration methods than when using equilibrium dialysis.

Indirect Methods for Estimating Free Thyroid Hormones

Two-step and one-step immunoassays estimate free hormone concentrations by using antibody extraction techniques. They are subdivided into sequential two-step assays and simultaneous one-step ("analogue") assays. The analogue methods are no longer used, and the sequential two-step assays are preferred. Each procedure involves the direct incubation of serum with a specific anti-T_4 or anti-T_3 antibody, during which thyroid hormones reach a new equilibrium with all of the binders present. A slight decrease in free hormone concentration occurs, but is insignificant if the antibody sequesters less than 5% of the total amount of hormone present in the specimen. Thus the amount of immunoextracted T_4 or T_3 closely approximates the undisturbed free hormone concentration that preexists in serum at equilibrium.

Comments

Estimates of FT_4 and FT_3 generally give reliable results in (1) healthy subjects, (2) hyperthyroid and hypothyroid patients, and (3) patients with only mild binding protein abnormalities. Results are comparable with those of reference methods, such as those that use direct equilibrium dialysis. In certain clinical conditions, free hormone estimate methods may give abnormal results that differ from the generally accepted reference values. These abnormalities are commonly encountered in euthyroid patients who show significant changes in T_4 or T_3 binding to serum proteins.

Measurement of Thyroxine-Binding Globulin

Modern TBG methods measure its concentration directly using a variety of immunochemical approaches. For example, one competitive, heterogeneous method measures the competition between endogenous TBG and labeled TBG for binding to an immobilized anti-TBG antibody. Another assay utilizes a solid-phase second antibody; bound conjugate that is measured by chemiluminescence after the addition of Luminol and hydrogen peroxide. A third immunoassay is based on enhanced microparticle turbidimetry, in which the presence of endogenous antigen inhibits the cross-linking of antigen-microparticle complexes by anti-TBG antibody, reducing the turbidity of the reaction mixture.

Measurement of Thyroglobulin

Both competitive and noncompetitive immunoassays have been applied to Tg measurement.[12,18] Present-day

competitive immunoassays typically incubate the serum with anti-Tg antibody; this is followed by the addition of ^{125}I-labeled Tg. The Tg–anti-Tg complex is precipitated by a second antibody, separating antibody-bound from free ^{125}I-labeled Tg. Noncompetitive (sandwich) immunoassays for Tg have been developed using a variety of labels. Technical improvements in such assays have resulted in the availability of a new generation of Tg assays with enhanced lower limits of detection.[12]

A technical problem with Tg assays is interference from TGAs in the patient's blood that limits the accurate measurement of Tg. Consequently, it is standard practice to search for TGA whenever Tg is measured. When TGAs are detected, the TGA concentration may be useful as a secondary marker of the mass of thyroid tissue present in the patient. Of note is the fact that anti-Tg autoantibodies are much more common in thyroid cancer patients than in the general population.[10] For example, TGAs are reported in 15% to 35% of thyroid cancer patients. Consequently, Tg measurements should not be used as tumor markers in the clinical management of patients with demonstrated TGA.

Determination of Thyroid Autoantibodies

Increased circulating concentrations of thyroid autoantibodies are found in a variety of thyroid disorders and in other autoimmune diseases and certain malignancies. These autoantibodies are directed against several thyroid and thyroid hormone antigens, including (1) Tg (TgAb), (2) thyroid peroxidase antibody (TPOAb), (3) the TSH receptor (TRAb), (4) TSH, (5) T_4, and (6) T_3. Of these autoantibodies, measurement of TPOAb is the test most often used to evaluate thyroid autoimmune diseases.

TPOAs and Tg autoantibodies are detected by a variety of methods, including (1) indirect immunofluorescence, (2) the agar gel diffusion precipitin technique, (3) agglutination (hemagglutination or latex particle agglutination), (4) RIA, (5) complement fixation, (6) ELISA techniques, and (7) chemiluminescence-based immunometric assays.[20]

Review Questions

1. What is the most common type of laboratory assay that is widely used to assess thyroid hormone concentrations?
   a. Ultrafiltration.
   b. Immunoassay.
   c. Potentiometry.
   d. Estimation from using a formula.
2. What stimulates the uptake of iodide by the thyroid gland for thyroid hormone synthesis?
   a. Thyroid-stimulating hormone (TSH)
   b. Thyroxine (T_4)
   c. Tyrosine
   d. Thyroiditis
3. What causes primary hypothyroidism?
   a. The absence or dysfunction of the thyroid gland.
   b. Increased TSH.
   c. A pituitary disorder.
   d. A hypothalamus disorder.
4. Hyperthyroidism is also referred to as
   a. Athyreosis.
   b. Myxedema.
   c. Thyrotoxicosis.
   d. Exophthalmos.
5. What is the function of thyroid hormones?
   a. Inhibit the secretion of growth hormone.
   b. Solely regulate reproductive processes in male and females.
   c. Maintain water homeostasis.
   d. Regulate carbohydrate, lipid, and protein metabolism within cells.
6. Secondary hypothyroidism is indicated by which one of the following sets of lab results?
   a. Increased T_4, and decreased TSH
   b. Increased T_4, and increased TSH
   c. Decreased T_4, and increased TSH
   d. Decreased T_4, and decreased TSH
7. The thyroid gland produces all of the following hormones except which one of the following hormones?
   a. TSH.
   b. Calcitonin.
   c. Thyroxine (T_4).
   d. Triiodothyronine (T_3).
8. What is the amino acid precursor of T_4?
   a. Threonine.
   b. Tyrosine.
   c. Thyronine.
   d. Alanine.
9. What is the technique of choice to measure T_3 in body fluids?
   a. Nephelometry.
   b. Potentiometry.
   c. Immunoassay.
   d. Atomic absorption.
10. Which one of the following analytes is most sensitive for the early detection of primary thyroid gland failure?
    a. Thyroxine (T_4)
    b. TSH
    c. Thyroglobulin (Tg)
    d. Thyroid-binding globulin (TBO)

CHAPTER

43 Reproduction-Related Disorders*

Mari L. DeMarco, Ph.D., and Ann M. Gronowski, Ph.D.

Objectives

1. Define the following:
   - Amenorrhea
   - Androgen
   - Dehydroepiandrosterone sulfate (DHEAS)
   - Gonadotropin-releasing hormone (GnRH)
   - Gynecomastia
   - Hirsutism
   - Infertility
   - Inhibin
   - Menopause
   - Polycystic ovary syndrome (PCOS)
   - Precocious puberty
   - Virilization
2. Describe the hypothalamic-pituitary control of the gonads.
3. For each of the hormones listed below, state and describe sites of synthesis and action on target organ, transport, physiological function, metabolism, and regulation in both males and females:
   - Estrogens
   - Follicle stimulating hormone
   - Gonadotropin-releasing hormone (GnRH)
   - Luteinizing hormone (LH)
   - Progesterone
   - Testosterone
4. Diagram the phases of the normal female reproductive cycle and include the specific hormones involved in each phase; describe the roles of these hormones and the control mechanisms of each phase.
5. List the hormone changes, symptoms, and causes of the following disorders:
   - Amenorrhea
   - Erectile dysfunction
   - Hyper- and hypogonadotropic hypogonadism
   - Infertility
   - Kallmann syndrome
   - Polycystic ovary syndrome (PCOS)
   - Precocious puberty
6. Discuss the role of the clinical laboratory in the evaluation of ovulation, amenorrhea, menopause, male/female infertility, and other reproductive endocrine disorders; include specific laboratory tests used and results of these tests.
7. Assess and solve case studies related to reproductive endocrinology and disorders.

Key Words and Definitions

Androgen insensitivity syndrome (AIS) A genetic disorder in which XY male fetuses are unresponsive to androgens and are born looking externally like normal females.

Amenorrhea The absence of menstruation.

Androstenedione An androgenic steroid produced by the (1) testes, (2) adrenal cortex, and (3) ovary. It is converted metabolically to testosterone and other androgens.

Congenital adrenal hyperplasia (CAH) A genetic disorder characterized by a deficiency of any one of several enzymes needed to make cortisol from cholesterol; symptoms arise from lack of the hormones cortisol and aldosterone and altered production of sex hormones; the latter may affect sexual development before birth.

Corpus luteum A yellow glandular mass in the ovary formed by an ovarian follicle that has matured and discharged its ovum; secretes progesterone.

Corticosteroid-binding globulin An α-globulin that binds unconjugated corticosteroid and transports it in the plasma.

Dehydroepiandrosterone (DHEA) A hormone produced by the adrenal glands. After being secreted, it circulates in the bloodstream as DHEA-sulfate (DHEAS) and is converted as needed into other hormones.

Dihydrotestosterone (DHT) A powerful androgenic hormone that is formed in peripheral tissue by the action of the enzyme 5α-reductase on testosterone.

*The authors gratefully acknowledge the original contribution of R. J. Whitley, A. W. Meikle, N. B. Watts, T.S. Isbell, and E. Jungheim, on which portions of this chapter are based.

Key Words and Definitions—cont'd

Estradiol (E_2) and Estriol (E_3) Estrogenic hormones produced by the (1) ovaries, (2) corpus luteum, and during pregnancy by the (3) placenta. The adrenal glands and testes (in men) are also believed to secrete smaller quantities of estrogens.

Estrone (E_1) A natural estrogenic hormone that is a ketone found in the body chiefy as a metabolite of estradiol (E_2); it is also secreted especially by the ovaries.

Female athletic triad A group of findings commonly seen in young female athletes, consisting of (1) eating disorders, (2) amenorrhea, and (3) osteoporosis.

Follicle A pouch-like sac that is on the surface of the ovary and contains the maturing ovum (egg); also called Graafan follicle.

Follicle-stimulating hormone (FSH) An anterior pituitary peptide that stimulates the development of Graafian follicles in the female and spermatozoa in the male.

Gonad A gamete-producing organ (an ovary or a testis).

Gonadotropin-releasing hormone (GnRH) A peptide that is released from the brain and stimulates the pituitary gland to secrete gonadotrophic hormones that in turn act on the sex glands.

Gynecomastia Excessive development of the male mammary glands.

Hirsutism Abnormal hairiness, especially an adult male pattern of hair distribution in females.

Human chorionic gonadotropin (hCG) A hormone produced early in pregnancy by the placenta.

hCG stimulation test A test administered to assess the ability of the testes to respond to hCG and produce testosterone.

3β-Hydroxysteroid dehydrogenase deficiency An inherited disorder that affects hormone-producing glands, including the gonads (ovaries in females and testes in males) and the adrenal glands.

11β-Hydroxylase deficiency A type of congenital adrenal hyperplasia due to 11β-hydroxylase deficiency; it is one of a group of disorders (collectively called congenital adrenal hyperplasia) that affect the adrenal glands.

21-Hydroxylase deficiency A deficiency of this enzyme results in decreased cortisol synthesis and increased synthesis of male hormones by the adrenal; three types are described: (1) salt-wasting, (2) simple virilizing, and (3) nonclassical.

Hyperandrogenism A medical condition characterized by excessive production and/or secretion of androgens.

Hypergonadotropic hypogonadism A condition characterized by (1) defective development of ovaries or testes, (2) excess pituitary gonadotropin secretion, and (3) delayed sexual development and growth delay.

Hyperprolactinemia A condition characterized by the presence of abnormally-high levels of prolactin.

Hypertrichosis Excessive growth of hair.

Hypogonadotropic hypogonadism A condition with impaired production of the hormones (LH and FSH) that stimulate the gonads; lack of LH and FSH leads to decreased sex hormone production by the gonads and accompanying symptoms.

Infertility The inability to conceive after 1 year of unprotected intercourse.

Inhibin A peptide hormone secreted by the follicular cells of the ovary and the Sertoli cells of the testis that inhibits secretion of follicle stimulating hormone (FSH) from the anterior pituitary.

Inhibin A Ovary-produced inhibin A is an important negative feedback hormone that suppresses pituitary secretion of FSH during the late follicular and luteal phases of the menstrual cycle.

Klinefelter syndrome A condition in a male characterized by (1) two X and one Y chromosomes, (2) infertility, (3) small testicles, (4) sparse facial and body hair, and (5) enlarged breasts.

Late-onset 21-hydroxylase deficiency A condition due to 21-hydroxylase deficiency. It is a common, milder form of congenital adrenal hyperplasia (CAH) characterized by a later onset of androgen excess symptoms seen in females and precocious pseudopuberty in both sexes; also known as non classical congenital adrenal hyperplasia.

Leydig cell A type of cell in the testes that secretes testosterone.

LH surge A sharp increase in serum concentrations of luteinizing hormone seen near the middle of the menstrual cycle about one to two days before ovulation.

Luteinizing hormone (LH) A hormone produced by the anterior lobe of the pituitary gland that stimulates ovulation and the development of the corpus luteum in the female and the production of testosterone by the interstitial cells of the testis in the male.

Menarche The establishment or beginning of the menstrual function.

Menopause Cessation of menstruation, which usually occurs around the age of 50.

Menses The monthly flow of blood from the genital tract of women.

Müllerian duct agenesis A congenital malformation characterized by a failure of the Müllerian duct to develop, with resultant absence or malformation of the vagina and/or uterus.

Müllerian duct Either of two embryonic tubes extending along the mesonephros that become the uterine tubes, uterus, and part of the vagina in the female and that form the prostatic utricle in the male.

Oligomenorrhea Menses occurring at intervals longer than 35 days.

Ovaries The paired female reproductive organs that produce ova (eggs), estrogens and progesterone.

Placenta A fetomaternal organ that is characteristic of true mammals during pregnancy; its functions include (1) transport of nutrients to the fetus, (2) transport of waste from the fetus, and (3) exchange of gases (oxygen and carbon dioxide) between the mother and fetus.

Polycystic ovary syndrome (PCOS) A female condition that is characterized by multiple ovarian follicles and increased androgen production.

Precocious puberty Early development of secondary sex characteristics; in girls generally before age 8 and in boys before age 9.

Primary ovarian insufficiency (POI) A condition in which the ovary fails to function adequately in a woman younger than 40 years.

Progesterone The principal progestational hormone liberated by the (1) corpus luteum, (2) adrenal cortex, and (3) placenta, whose function is to prepare the uterus for the implantation and development of the fertilized oocyte.

Progestational Preceding or promoting pregnancy; the phase of the menstrual cycle after ovulation; related to the characteristic actions of progesterone.

Key Words and Definitions—cont'd

Prolactin (PRL) A pituitary hormone that stimulates and maintains the secretion of milk.

Pseudohermaphroditism The condition of having the gonads and karyotype of one sex and external genitalia that is of the other sex or is ambiguous.

Pseudoprecocious puberty Development of secondary sex characters and reproductive organs that is not associated with pubertal levels of gonadotropins and gonadotropin-releasing hormone. Also called GnRH-independent precocious puberty.

Pure gonadal dysgenesis An intersex disorder characterized by 46,XX chromosomes and normal external female genitalia at birth.

Sertoli cell Any of the elongated, striated cells of the seminiferous tubules of the testis, to which spermatids attach for nourishment during spermatogenesis.

Sertoli cell–only syndrome A condition characterized by congenital absence of germinal epithelium from the seminiferous tubules, which contain only Sertoli cells, resulting in sterility due to the absence of living sperm cells in the semen. Also called Del Castillo syndrome.

Sex hormone–binding globulin (SHBG) A glycoprotein that binds to sex hormones, specifically androgens and estrogens.

Sperm protein SP-10 A sperm acrosomal protein, specific to the testis, that is believed to play an important role in egg-sperm binding.

Testis The male gonad, either of two oval reproductive glands located in the scrotum.

Testosterone The principal androgenic hormone, produced by the Leydig cells of the testes in response to stimulation by LH of the anterior pituitary gland.

Turner syndrome A chromosomal disorder affecting females wherein one of the two X-chromosomes is defective or completely absent.

Virilization The induction or development of male secondary sex characteristics; especially the induction of such changes in the female.

Reproductive endocrinology encompasses the hormones of the hypothalamic-pituitary-gonadal axis, as well as the adrenal glands (see Chapters 40 and 41). These hormones are crucial for reproductive function and include (1) **gonadotropin-releasing hormone (GnRH)**, (2) **luteinizing hormone (LH)**, (3) **follicle-stimulating hormone (FSH)**, and (4) a multitude of sex steroids. The sex steroids are synthesized by the (1) **ovaries**, (2) **testes**, and (3) adrenal glands and are responsible for the manifestation of primary and secondary sex characteristics.

Male Reproductive Biology

The male reproductive system consists of (1) testes, (2) a penis, and (3) related glands, such as the prostate and Cowper glands (Figure 43-1).

Biological Functions

The function of the testes is to synthesize sperm and androgens. Sertoli and Leydig cells play key roles in this process. For example, **Sertoli cells** in the seminiferous tubules of the testes have a crucial role in sperm maturation and secrete **inhibin**, a glycoprotein that inhibits the pituitary secretion of FSH.[9] Surrounding the seminiferous tubules are the interstitial **Leydig cells**, the primary site of androgen production. The principal androgen in the human male is **testosterone**, which is required for (1) sexual differentiation, (2) spermatogenesis, and (3) promotion and maintenance of sexual maturity at puberty.

Role of the Hypothalamic-Pituitary-Gonadal Axis

GnRH is a decapeptide synthesized in the hypothalamus and transported to the anterior pituitary gland, where it stimulates the release of both FSH and LH (Figure 43-1).

In adult men, (1) GnRH, (2) LH, and (3) FSH are secreted in pulsatile patterns with higher concentrations found in the

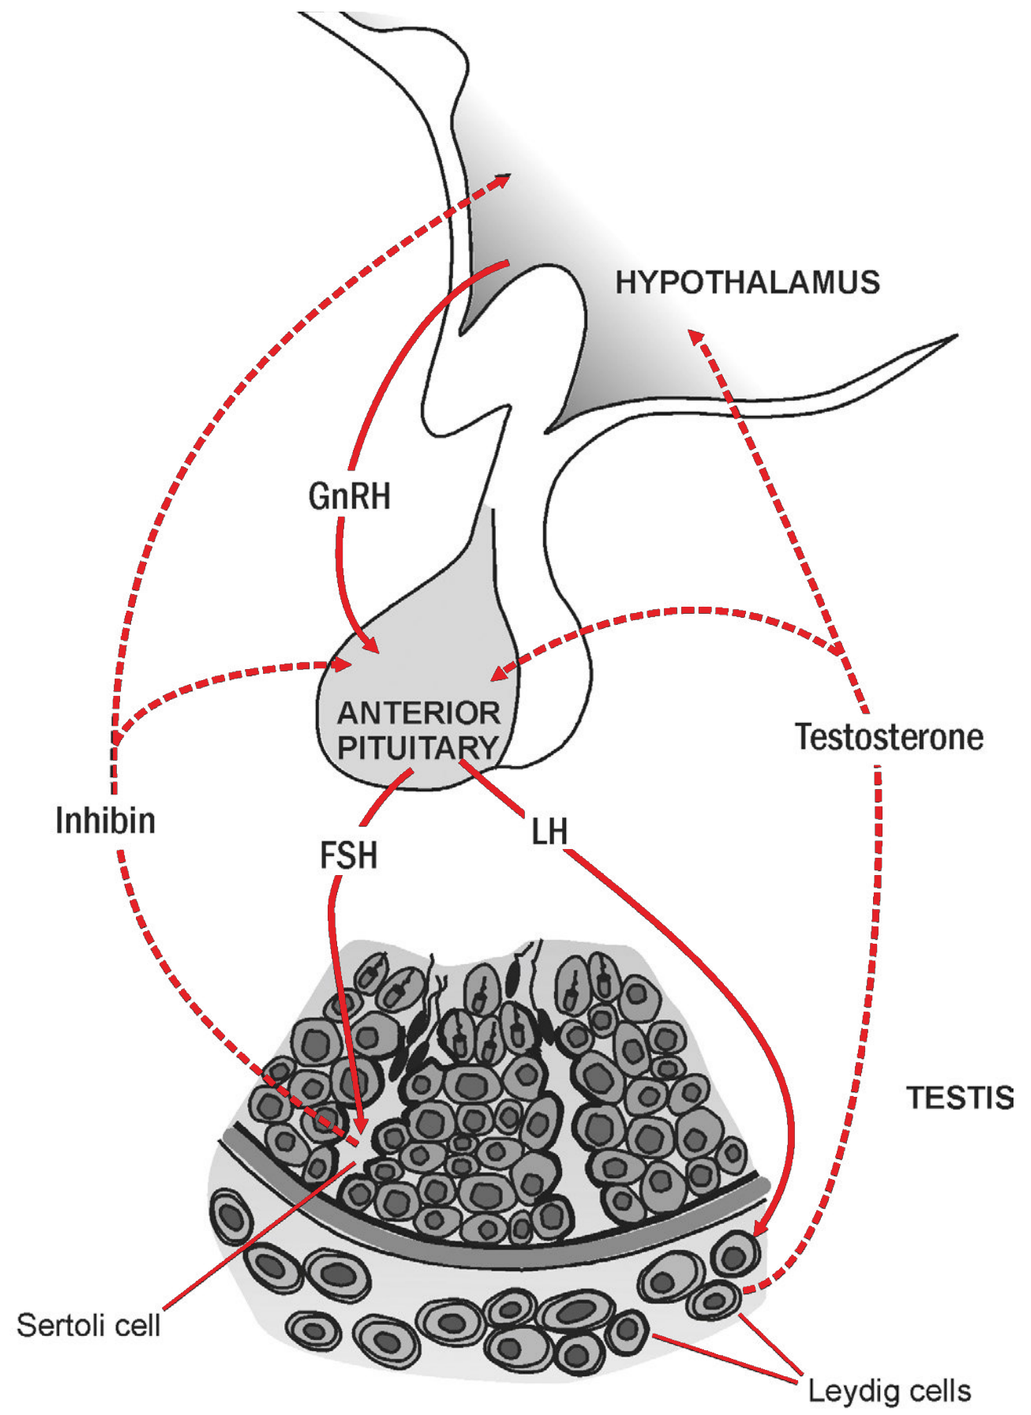

Figure 43-1 Summary of the endocrine control of the testis. Dashed lines indicate inhibitory effects, and solid lines stimulatory effects. FSH, Follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone.

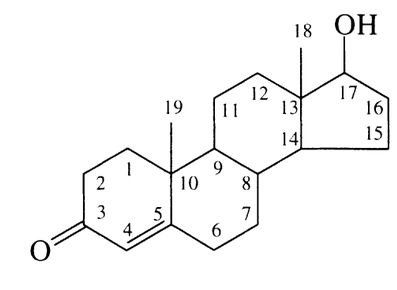
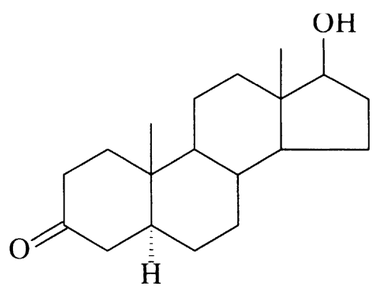


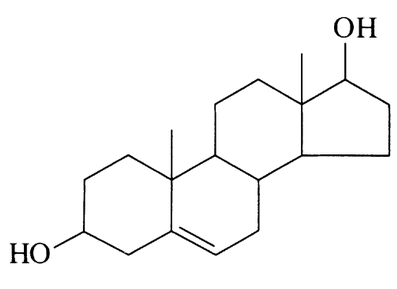
early morning hours and lower concentrations in the late evening. LH acts on Leydig cells to stimulate the conversion of cholesterol to pregnenolone. FSH acts on Sertoli cells and spermatocytes and is central to the initiation (in puberty) and maintenance (in adulthood) of spermatogenesis. Sex steroids and inhibin provide negative feedback control of LH and FSH secretion, respectively. LH secretion is inhibited by testosterone and by its metabolites, **estradiol (E_2)** and **dihydrotestosterone (DHT)**. Plasma FSH may be increased in disorders in which Sertoli cell numbers and inhibin concentrations are reduced. Likewise, a reduction in the number of Leydig cells and testosterone secretion leads to increased concentrations of LH.

Androgens



Androgens are a group of C-19 steroids (Figure 43-2) responsible for masculinization of the genital tract and development and maintenance of male secondary sex characteristics. Testosterone is the principle androgen secreted in men.

Biosynthesis of Testosterone



Testosterone is synthesized primarily by the Leydig cells of the testes (95%) and, to a lesser extent (≈5%) via peripheral conversion from the precursors **dehydroepiandrosterone (DHEA)** and **androstenedione** (which are synthesized in the adrenal glands). Synthesis of androgens begins with formation of pregnenolone from cholesterol. Following the formation of pregnenolone, four additional enzymatic steps are required to convert cholesterol to testosterone (Figure 43-3).

Figure 43-2 Chemical structure of androgens.

Androgen Transport in Blood

Testosterone and DHT circulate in plasma freely (≈2% to 3%) or bound to plasma proteins. Binding proteins include the specific **sex hormone–binding globulin (SHBG)** and nonspecific proteins, such as albumin. SHBG has low capacity for steroids but binds with very high affinity, whereas albumin has high capacity but low affinity. Testosterone and SHBG concentrations peak in the early morning (0400-0800 hours) and are at their lowest concentration in the evening (1600-2000 hours).

The biologically active fraction includes free testosterone and possibly albumin-bound testosterone. Consequently, the bioavailable testosterone (free + albumin-bound) is thought to be ≈35% of the total quantity.[10] Concentrations of bioavailable testosterone correlate with those of free testosterone.

Metabolism of Testosterone

Circulating testosterone serves as a precursor for the formation of two additional active metabolites. As shown in Figure 43-3, testosterone is converted to estradiol and to DHT by 5α-reductase or to estrogen by aromatase.[10]

DHT is thought to be (1) the essential androgen responsible for formation of primary sex characters in males during embryogenesis, (2) for development of most male secondary sex characters at puberty, and (3) for adult male sexual function. It is formed in androgen target tissues such as the skin and prostate, whereas aromatization occurs in many tissues, especially the liver and adipose tissue. Peripheral aromatization occurs primarily in adipose tissue (of both men and women) because of the high concentration of aromatase in this tissue. The rate of extraglandular aromatization therefore increases with body fat.

DHT is metabolized to 3α-androstanediol (see Figure 43-3) and then is conjugated to form 3α-androstanediol glucuronide. Serum concentrations of 3α-androstanediol glucuronide or 3α-androstanediol have bewen measured as markers of DHT production in peripheral tissues.

The main excretory metabolites of androstenedione, testosterone, and DHEA are shown in Figure 43-4. Except for epitestosterone, these catabolites constitute a group of steroids known as 17-ketosteroids (17-KSs); they are excreted primarily in the urine.

Testosterone Concentrations

Fetal testes produce testosterone around the seventh week of gestation with peak serum concentrations of ≈250 ng/dL observed at the beginning of the second trimester and with concentrations gradually returning to baseline by birth. Shortly after birth, the concentration of testosterone begins to increase, peaking again at ≈250 ng/dL at 2 to 3 months of age, and then falls to baseline again by 6 to 12 months. The concentration of

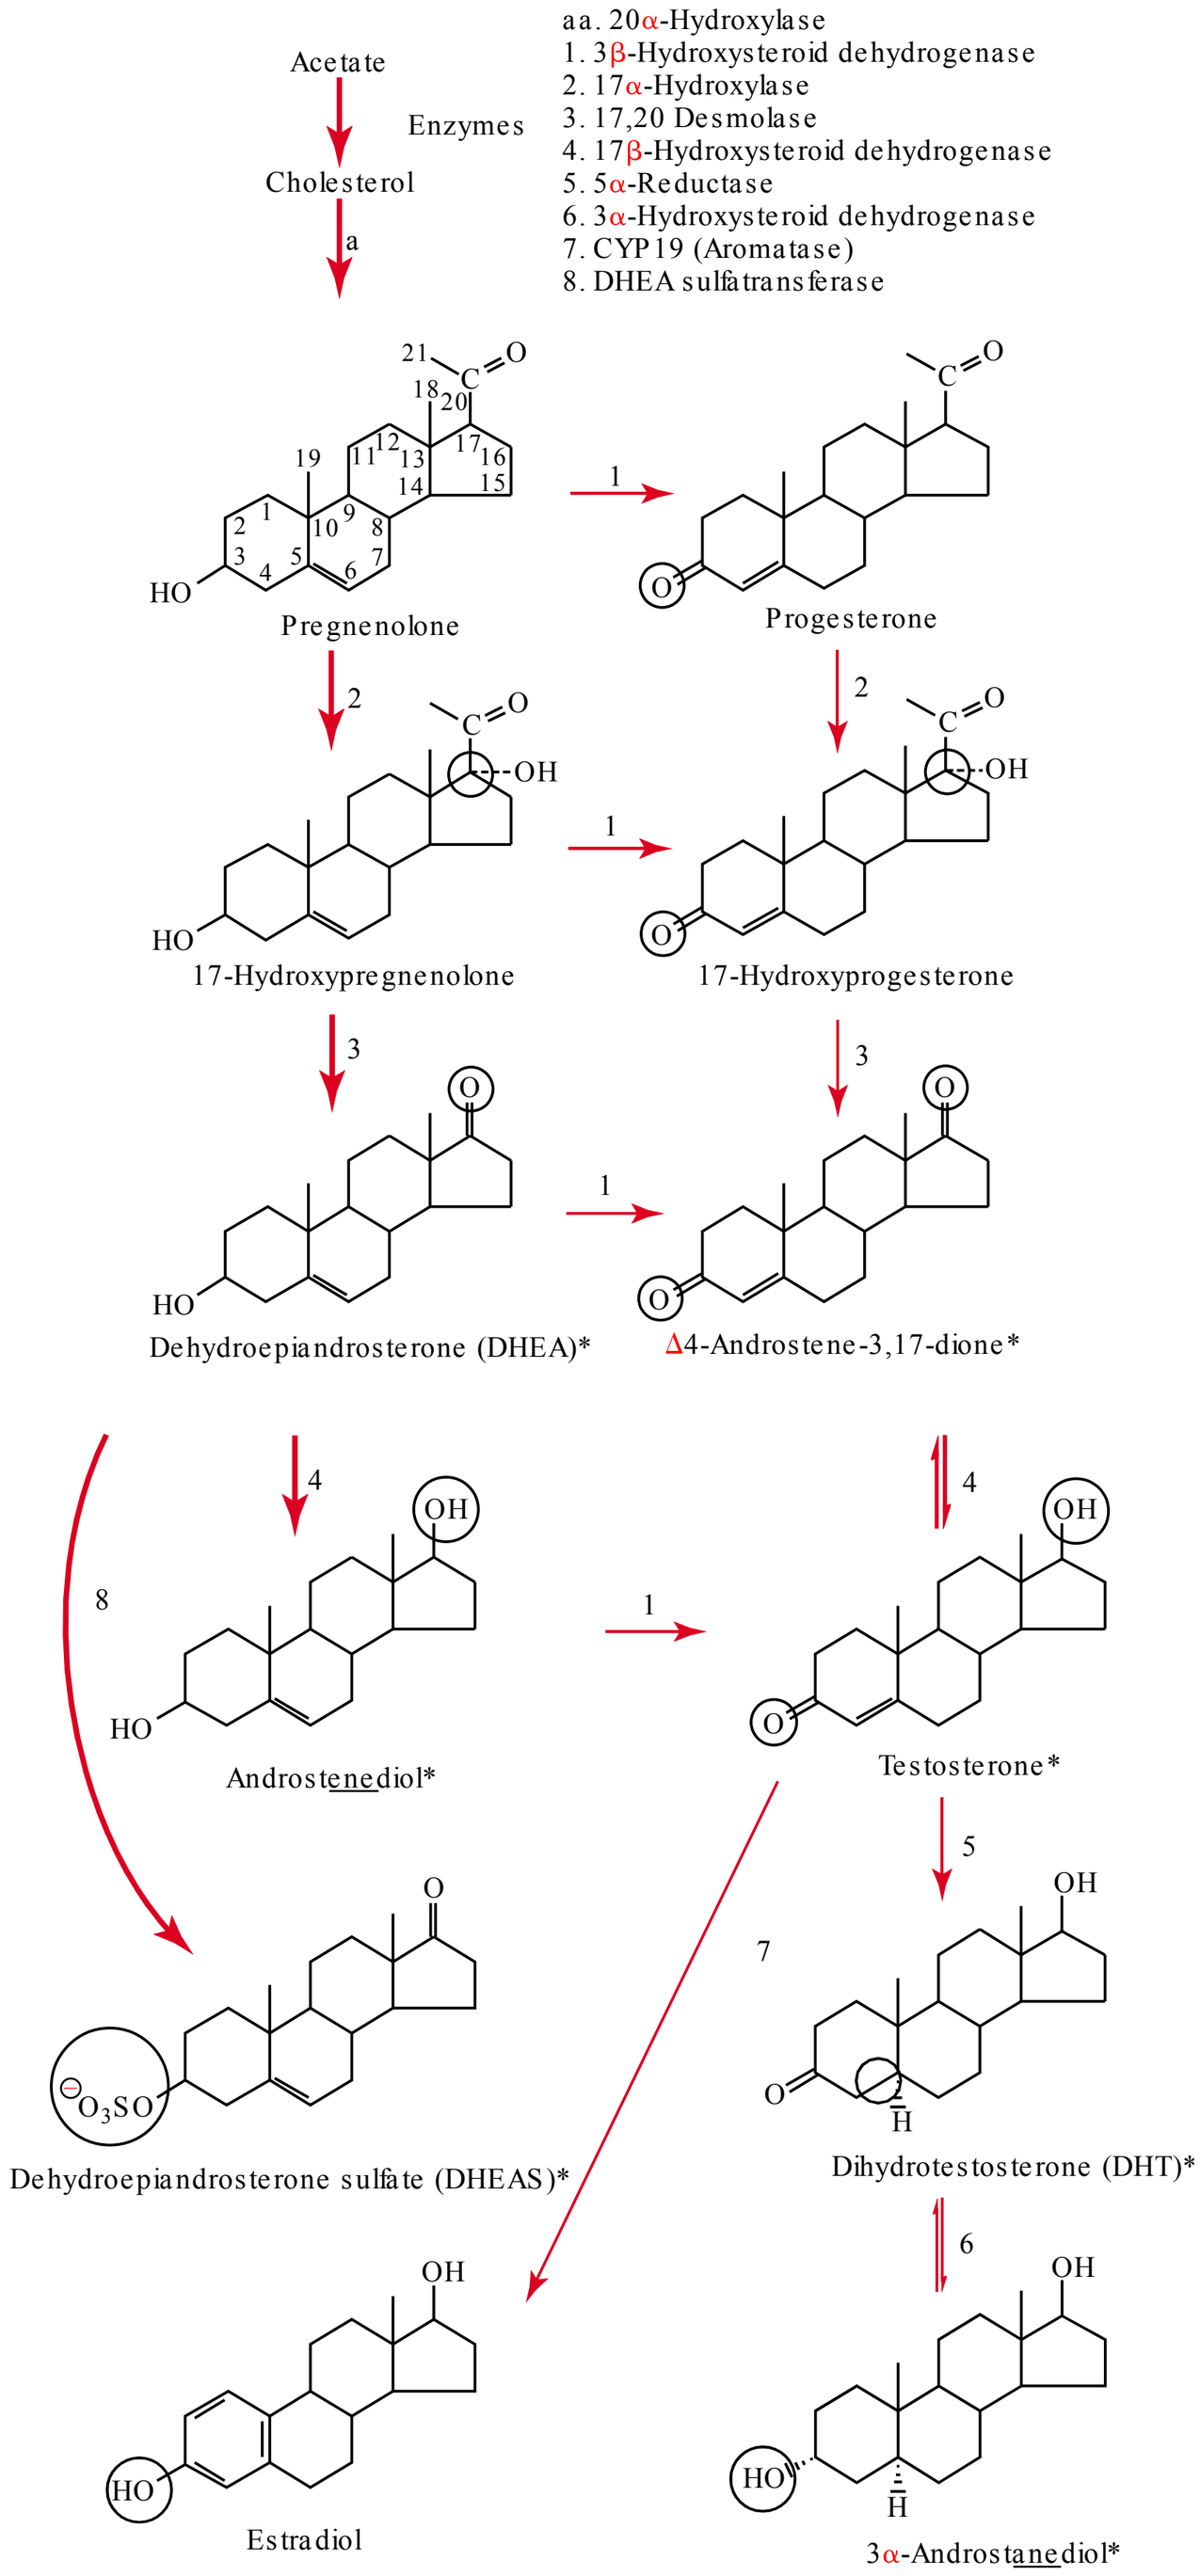

Figure 43-3 Biosynthesis of androgens (adrenal glands and testis). The heavy arrows indicate the preferred pathway. The encircled areas represents the sites of chemical change. *Denotes androgens.

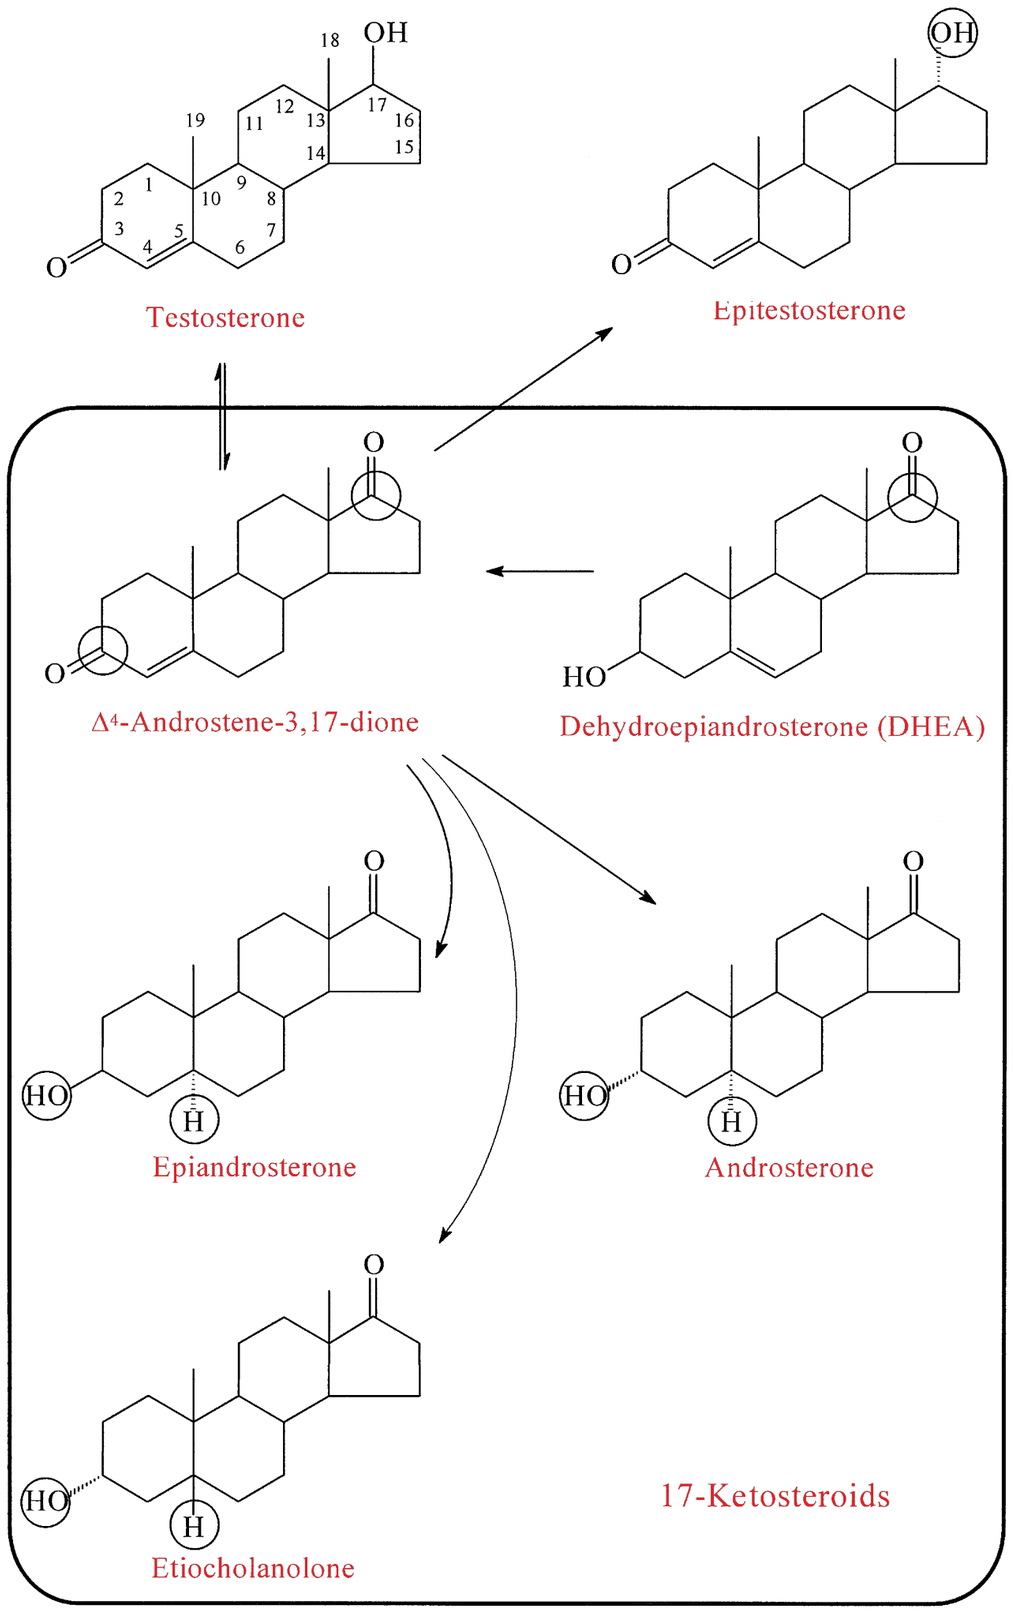

Figure 43-4 Catabolism of $C_{19}O_2$ androgens. The circled area represents the site of chemical change.

testosterone remains low (<50 ng/dL) until puberty, when the concentration of testosterone rises to 500 to 700 ng/dL. Testosterone remains at high concentrations through adulthood.

Men beyond the age of 30 to 40 years experience an age-dependent decrease in circulating testosterone concentration. T e 1.3% decrease per year in bioavailable serum testosterone is thought to be due to (1) a decrease in Leydig cell numbers, (2) decreased GnRH pulse amplitude, and (3) increases in SHBG. T ese decreases in circulating concentrations of testosterone, while typical, are now viewed as therapeutic targets when associated with clinical correlates of hypogonadism. Late-onset hypogonadism (LOH), and testosterone deficiency syndrome (TDS), represent the current nomenclature for the treatable syndrome characterized by an age related decline in serum testosterone accompanied by the clinical symptoms. Clinically, patients should exhibit symptoms suggestive of testosterone deficiency, such as (1) decreased libido, (2) erectile dysfunction, (3) decreased muscle mass and strength, (4) decreased bone mineral density, and (5) changes in mood. Patients should exhibit one to three of these symptoms with a concomitant low concentration of serum testosterone to fit various diagnostic criteria. Total serum testosterone is the most widely used biochemical parameter for assessment of hypogonadism. Measurement of free or bioavailable testosterone should be considered when total testosterone is not diagnostic despite the clinical presentation of hypogonadism. T is is particularly true in the setting of obesity and advanced age, where high concentrations of SHBG may mask a true deficit in testosterone. To assess whether hypogonadism is primary or secondary, serum LH should be measured; a serum **prolactin** (PRL) measurement is indicated when serum testosterone concentrations are lower than 5.2 nmol/L (150 ng/dL), or when secondary hypogonadism is suspected.

BOX 43-1 Male Reproductive Abnormalities

Hypogonadotropic Hypogonadism
Panhypopituitarism (congenital or acquired)
Hypothalamic syndrome (acquired or congenital)
- Structural defects (neoplastic, inflammatory, and infiltrative)
- Prader-Willi syndrome
- Laurence-Moon-Biedl syndrome

Gonadotropin-releasing hormone (GnRH) deficiency (Kallmann syndrome)
Hyperprolactinemia (prolactinoma or drugs)
Malnutrition and anorexia nervosa
Drug-induced suppression of luteinizing hormone (LH) (androgens, estrogens, tranquilizers, antidepressants, antihypertensives, barbiturates, cimetidine, GnRH analogs, and opiates)

Hypergonadotropic Hypogonadism
Acquired (irradiation, mumps orchitis, castration, and cytotoxic drugs)
Chromosome defects
- Klinefelter syndrome (47,XXY) and mosaics
- Autosomal and sex chromosomes, polyploidies
- True hermaphroditism

Defective androgen biosynthesis
- 20α-Hydroxylase (cholesterol 20,22-desmolase) deficiency
- 17,20-Lyase deficiency
- 3β-Hydroxysteroid dehydrogenase deficiency
- 17α-Hydroxylase deficiency
- 17β-Hydroxysteroid dehydrogenase deficiency

Testicular agenesis
Selective seminiferous tubular disease
Miscellaneous
- Noonan syndrome (short stature, pulmonary valve stenosis, hypertelorism, and ptosis)
- Streak gonads
- Myotonia dystrophica

Acute and chronic disease

Defects in Androgen Action
Complete androgen insensitivity syndrome (CAIS) (testicular feminization)
Partial androgen insensitivity syndrome (PAIS)
- 5α-Reductase deficiency (5-ARD)

Male Reproductive Abnormalities

A variety of abnormalities affect the male reproductive system before birth, in childhood, or in adulthood (Box 43-1). For the purposes of this chapter, they have been divided into the categories of (1) hypogonadotropic hypogonadism, (2) hypergonadotropic hypogonadism, (3) defects in androgen action, (4) erectile dysfunction, and (5) **gynecomastia**.

Hypogonadotropic Hypogonadism

Male hypogonadism is a condition caused by decreased function of the testes, which can lead to retardation of sexual development if manifested early in life. The disorder is classified as hypogonadotropic or hypergonadotropic depending on whether the pituitary gonadotropic hormones (LH and FSH) are decreased or increased.

Hypogonadotropic hypogonadism occurs when defects in the hypothalamus or pituitary prevent normal gonadal stimulation. Causative factors include (1) congenital or acquired panhypopituitarism, (2) hypothalamic syndromes, (3) GnRH deficiency, (4) **hyperprolactinemia,** (5) malnutrition or anorexia, and (6) iatrogenic causes. All of these abnormalities are associated with decreased testosterone and gonadotropin concentrations.

Kallmann syndrome, the most common form of hypogonadotropic hypogonadism, results from a deficiency of GnRH in the hypothalamus during embryonic development. It is characterized by hypogonadism and anosmia (loss of the sense of smell) in male or female patients. It is a congenital defect with several genetic causes that result in gonadotropic deficiency.

Hypergonadotropic Hypogonadism

Hypergonadotropic hypogonadism results from a primary gonadal disorder. Patients with primary testicular failure have increased concentrations of LH and FSH and decreased concentrations of testosterone. Causes for primary hypogonadism are categorized as (1) acquired causes (irradiation, castration, mumps orchitis, or cytotoxic drugs), (2) chromosome defects **(**such as **Klinefelter syndrome),** (3) defective androgen synthesis (20α-hydroxylase deficiency), (4) testicular agenesis, (5) seminiferous tubular disease, and (6) other miscellaneous causes. Aging is associated with gonadal failure, which leads to decreased testosterone secretion.[9]

Defects in Androgen Action

The most common and severe defect in androgen action is **androgen insensitivity syndrome (AIS)**, a disorder arising from mutations in the androgen receptor (AR) gene. AIS is classified as complete (CAIS) or partial (PAIS), depending on the amount of residual receptor function. Individuals with CAIS (formerly known as testicular feminization) have a male karyotype (46,XY) with female external genitalia and intra-abdominal testes. The circulating concentration of testosterone in these patients is greater than or equal to that of a healthy male, whereas LH concentrations are typically increased.

Males with 5α-reductase deficiency (5-ARD) have reduced efficiency of the conversion of testosterone to the more potent DHT. Because DHT leads to masculinization of external genitalia in utero, males with 5-ARD are born with ambiguous genitalia. High ratios of the circulating concentrations of testosterone to DHT are indicative of 5-ARD.

In patients with cryptorchidism or ambiguous genitalia, identification of abdominal **gonads** is essential for proper diagnosis and treatment. The presence of testicular tissue has traditionally been detected by measurement of Leydig cell testosterone production after stimulation with **human chorionic gonadotropin (hCG)**. In addition, serum inhibin and plasma anti-Müllerian hormone may offer a noninvasive evaluation of seminiferous tubular integrity.

Erectile Dysfunction

Erectile dysfunction (formerly referred to as impotence) is the persistent inability to develop or maintain a penile erection that is sufficient for intercourse and ejaculation in 50% or more of attempts.[8] Psychogenic erectile dysfunction is the most common diagnosis. Other causes include (1) vascular disease, (2) diabetes mellitus, (3) hypertension, (4) uremia, (5) neurologic disease, (6) hypogonadism, (7) hyperthyroidism, (8) hypothyroidism, (9) neoplasms, and (10) drugs. If no obvious explanation for erectile dysfunction is found, measurement of morning serum testosterone, LH, and thyroid-stimulating hormone (TSH) concentrations has been suggested. Elevated gonadotropin concentrations indicate primary hypogonadism. Total and even free testosterone concentrations may be within reference intervals, yet still may be subnormal for a given patient if found in the presence of elevated LH or FSH.

Gynecomastia

Gynecomastia, the benign growth of glandular breast tissue in men, is a common finding among males of varied ages. Gynecomastia, which is associated with an increase in the estrogen/androgen ratio, is commonly associated with three distinct periods of life. First, transient gynecomastia is found in 60% to 90% of all newborns because of high estrogen concentrations that cross the **placenta**. The second peak occurs during puberty in 50% to 70% of healthy boys. It is usually self-limited and may be due to a (1) low serum testosterone, (2) low DHT, or (3) high estrogen/androgen ratio. The last peak is found in the adult population, most frequently among men aged 50 to 80 years. Gynecomastia may be due to (1) testicular failure, resulting in an increased estrogen/androgen ratio, or to (2) increased body fat, resulting in increased peripheral aromatization of testosterone to E_2.

Gynecomastia may also develop as the result of (1) iatrogenic causes, (2) hyperthyroidism, or (3) liver disease. In cases of striking gynecomastia in which history and physical examination point to no specific disorder, measurements of (1) hCG, (2) E2, (3) testosterone, and (4) LH concentrations are appropriate. It is important to note that prolactin plays an important role in galactorrhea (milk production), but only an indirect role in gynecomastia.

Female Reproductive Biology

The female reproductive system consists of a (1) vagina, (2) uterus, (3) fallopian tubes, and (4) ovaries. The function of the ovaries is to produce ova and secrete the sex hormones **progesterone** and estrogen.

Biological Functions

Healthy female neonates possesses approximately 400,000 primordial **follicles**, each containing an immature ovum. During

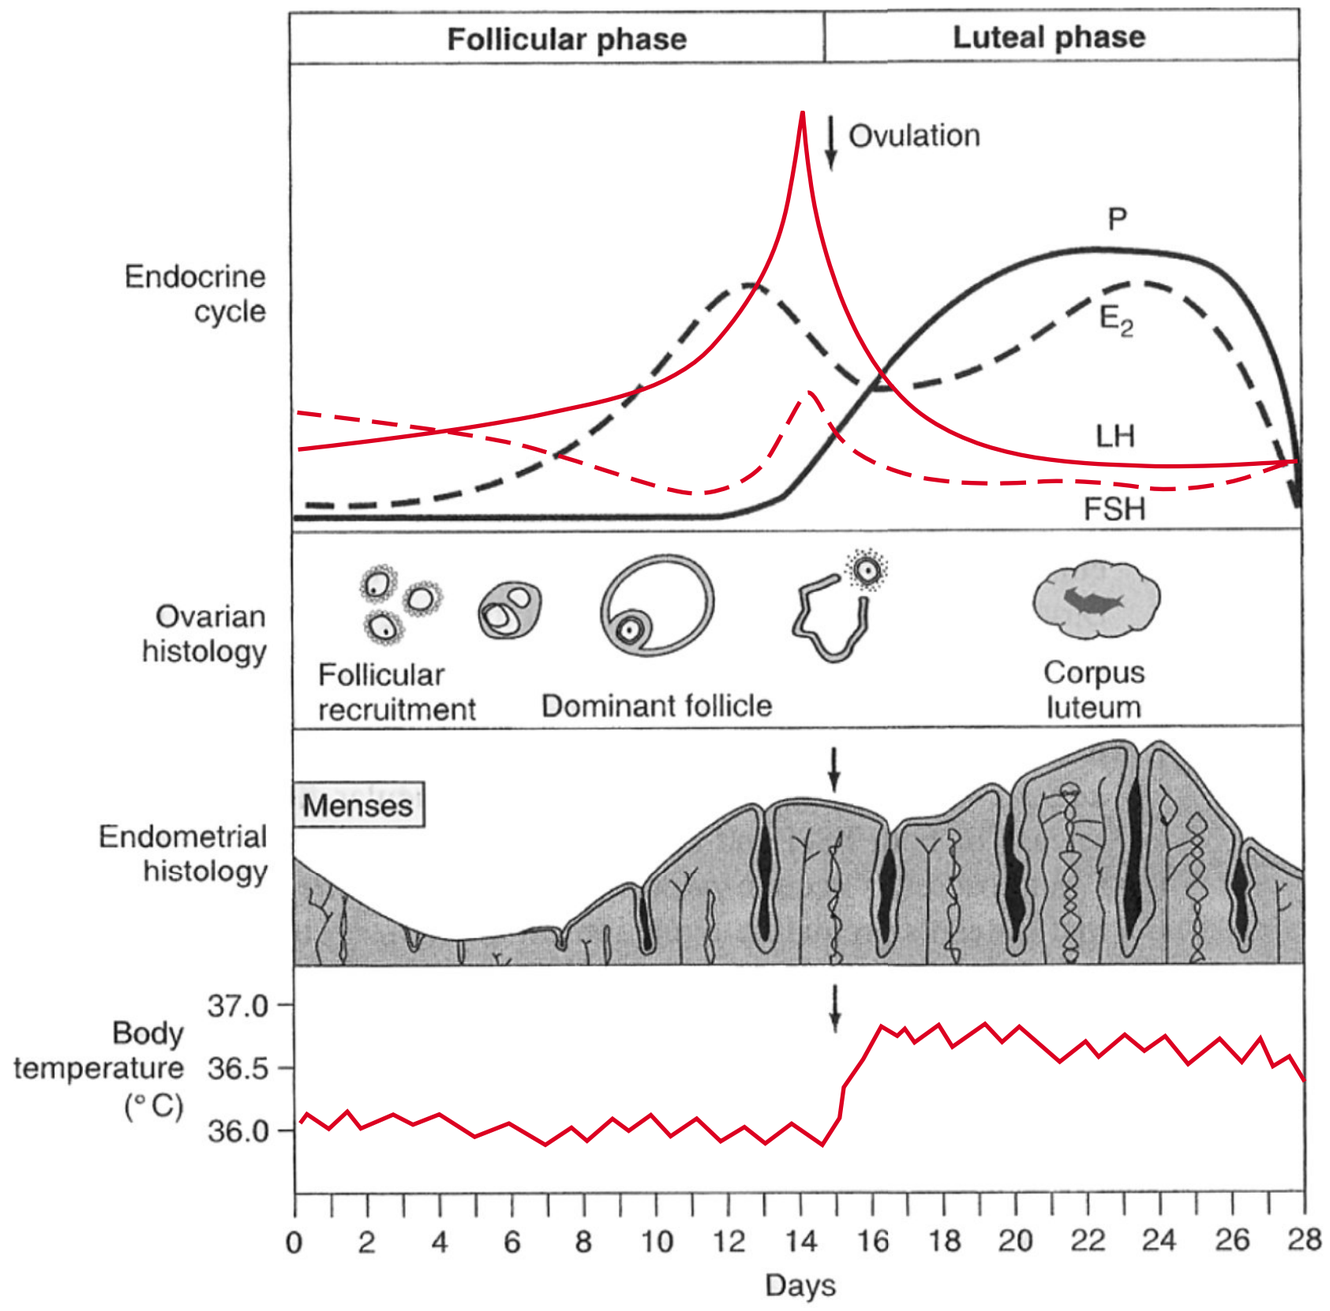

Figure 43-5 Hormonal, ovarian, endometrial, and basal body temperature changes throughout the normal menstrual cycle. (From Carr BR, Bradshaw KD. Disorders of the ovary and female reproductive tract. In: Braunwald E, Fauci A, Kasper D, Hauser SL, Longo DL, Jameson JL eds. Harrison's principles of internal medicine, 15th edition. New York, NY: McGraw-Hill, 2001:2158; used with permission.)

the reproductive life span of an adult woman, 300 to 400 follicles will reach maturity. A single mature follicle is produced during each normal menstrual cycle at approximately day 14 (Figure 43-5). The mature follicle undergoes ovulation by the process of rupture, thereby releasing the oocyte into the proximity of the fallopian tubes. The granulosa and theca cells of the follicle lining quickly proliferate to form the **corpus luteum** (yellow body). The luteal cells produce estrogen and progesterone. If fertilization and pregnancy occur, the corpus luteum persists and continues to produce estrogen and progesterone. If no pregnancy occurs, the corpus luteum regresses, and the next menstrual cycle begins.

During the follicular phase, the endometrial lining of the uterus increases in thickness and vascularity in response to increasing circulating concentrations of estrogen. After regression of the corpus luteum, menstruation begins, and the endometrium is shed in response to the withdrawal of progesterone.

Hypothalamic-Pituitary-Gonadal Axis

In adult women, a tightly coordinated feedback system exists between (1) hypothalamus, (2) anterior pituitary, and (3) ovaries to orchestrate menstruation. FSH serves to stimulate follicular growth, and LH stimulates ovulation and progesterone secretion from the developing corpus luteum (Figure 43-6).

Estrogens

Estrogens are responsible for the development and maintenance of female sex organs and female secondary sex

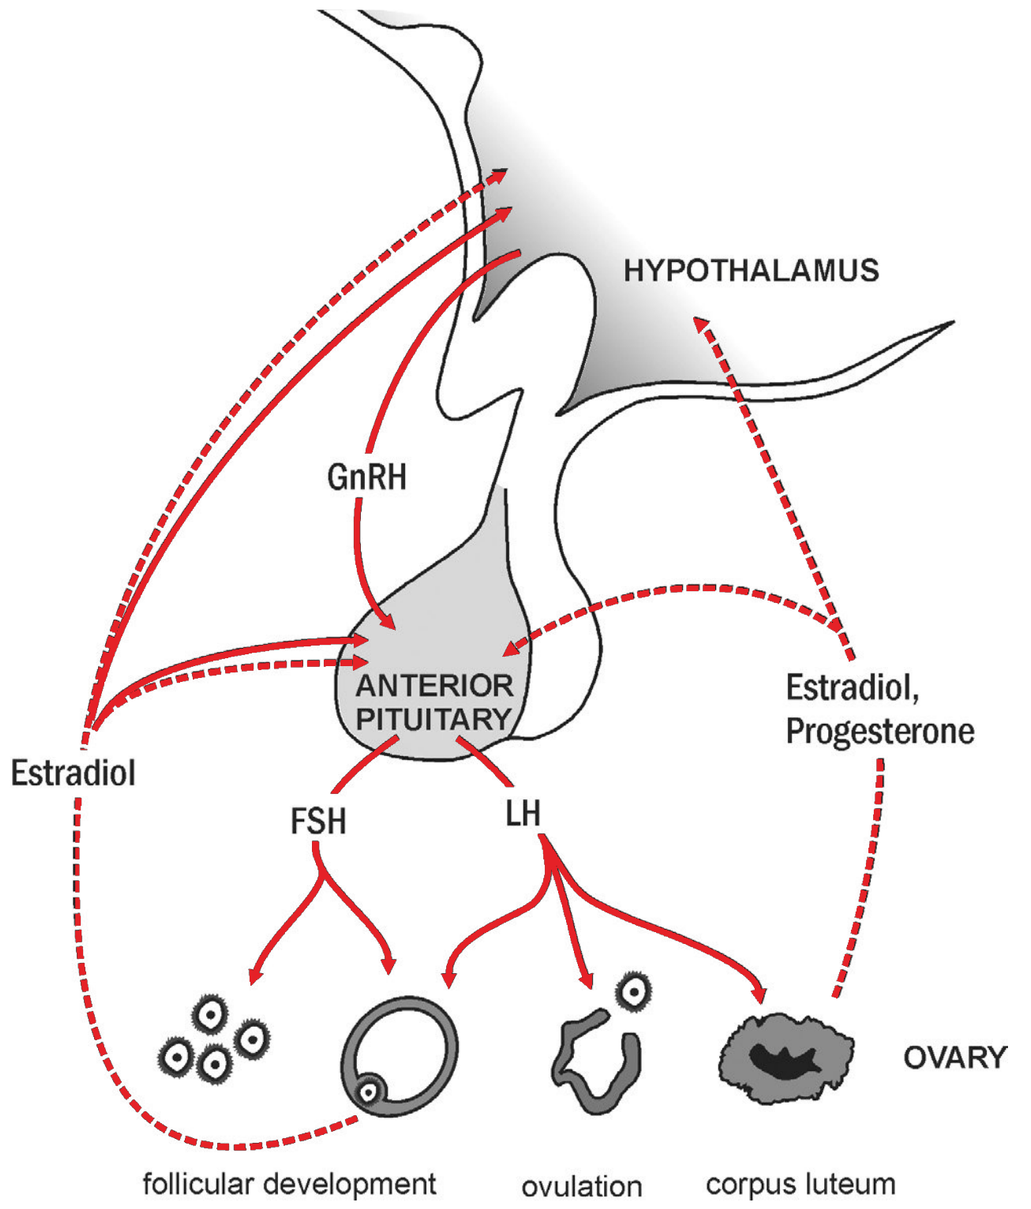

Figure 43-6 Summary of the endocrine control and changes in ovary and endometrium during the menstrual cycle. Dashed lines indicate inhibitory effects, and solid lines indicate stimulatory effects.

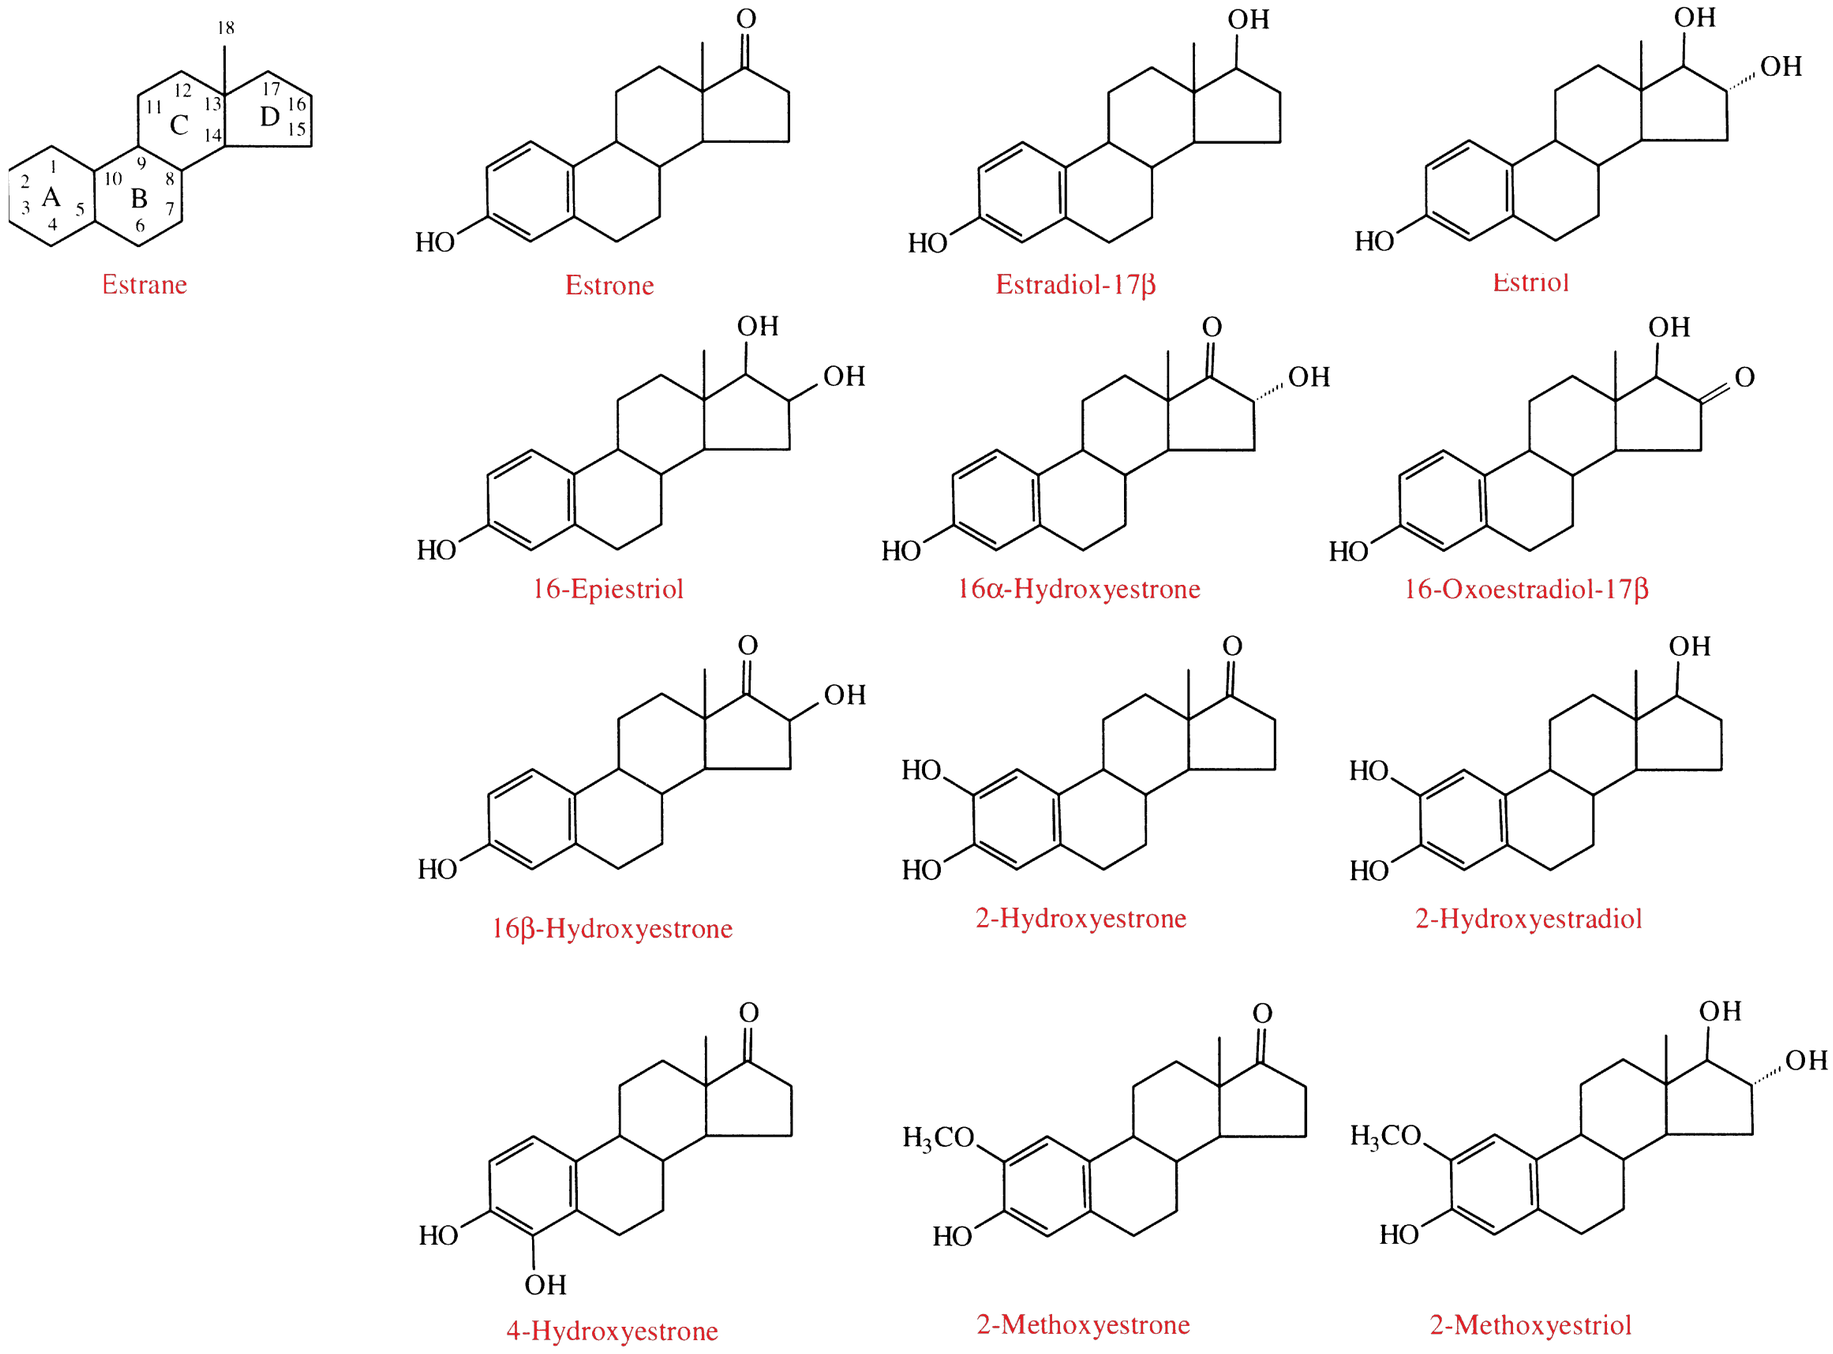

Figure 43-7 Structural formulas of important estrogens.

characteristics. In conjunction with progesterone, they participate in (1) regulation of the menstrual cycle, (2) breast and uterine growth, and (3) the maintenance of pregnancy.

Estrogens affect calcium homeostasis and have a beneficial effect on bone mass. Estrogens also increase concentrations of plasma proteins including (1) SHBG, (2) corticosteroid-binding globulin, and (3) thyroxine-binding globulin. Boys and girls have comparable concentrations of SHBG, but adult men have SHBG concentrations that are about one half those of adult women. Concentrations of plasma proteins that bind copper and iron are also elevated in response to estrogen, as are the concentrations of high-density lipoproteins.

Chemistry

The three most biologically active estrogens in order of potency are (1) **estrone (E_1)**, (2) E_2, and (3) **estriol (E_3)** (Figure 43-7). Chemically, estrogens are structural derivatives of the parent hydrocarbon estrane. All estrogens possess a phenolic hydroxyl group at C-3, which gives the compounds acidic properties, and lack a methyl group at C-10. In addition, estrogens may possess a ketone (E_1) or hydroxyl group (E_2) at position C-17. The phenolic ring A and the hydroxyl group at C-17 are essential for biological activity.

Biosynthesis

Estrogens are secreted primarily in healthy women by the (1) ovarian follicles, (2) corpus luteum, and during pregnancy by the (3) placenta. The adrenal glands and testes (in men) are also believed to secrete minute quantities of estrogens. The ovary synthesizes estrogens via aromatization of androgens (Figure 43-8). The healthy human ovary produces (1) estrogens, (2) progestagens, and (3) androgens. However, E_2 and progesterone are its primary secretory products. Because the ovary lacks both the 21-hydroxylase and 11β-hydroxylase enzymes, glucocorticoids and mineralocorticoids are not produced in the ovary.[3,12] More than 20 estrogens have been identified, but only 17β-estradiol and E_3 are routinely measured clinically. The most potent estrogen secreted by the ovary is 17β-estradiol. Because it is derived almost exclusively from the ovaries, its measurement is often considered sufficient for evaluation of ovarian function.

Estrogens are also produced by peripheral aromatization of androgens, primarily androstenedione. In healthy men and women, ≈1% of secreted androstenedione is converted to E_1. Although the ovaries of postmenopausal women do not secrete estrogens, these women have significant blood concentrations of E_1 originating from the peripheral conversion of adrenal androstenedione. Because a major site of this conversion is adipose tissue, E_1 is increased in obese postmenopausal women, sometimes yielding enough estrogen to produce bleeding.

Biosynthesis during Pregnancy

The biosynthesis of estrogens differs qualitatively and quantitatively in pregnant women compared with nonpregnant

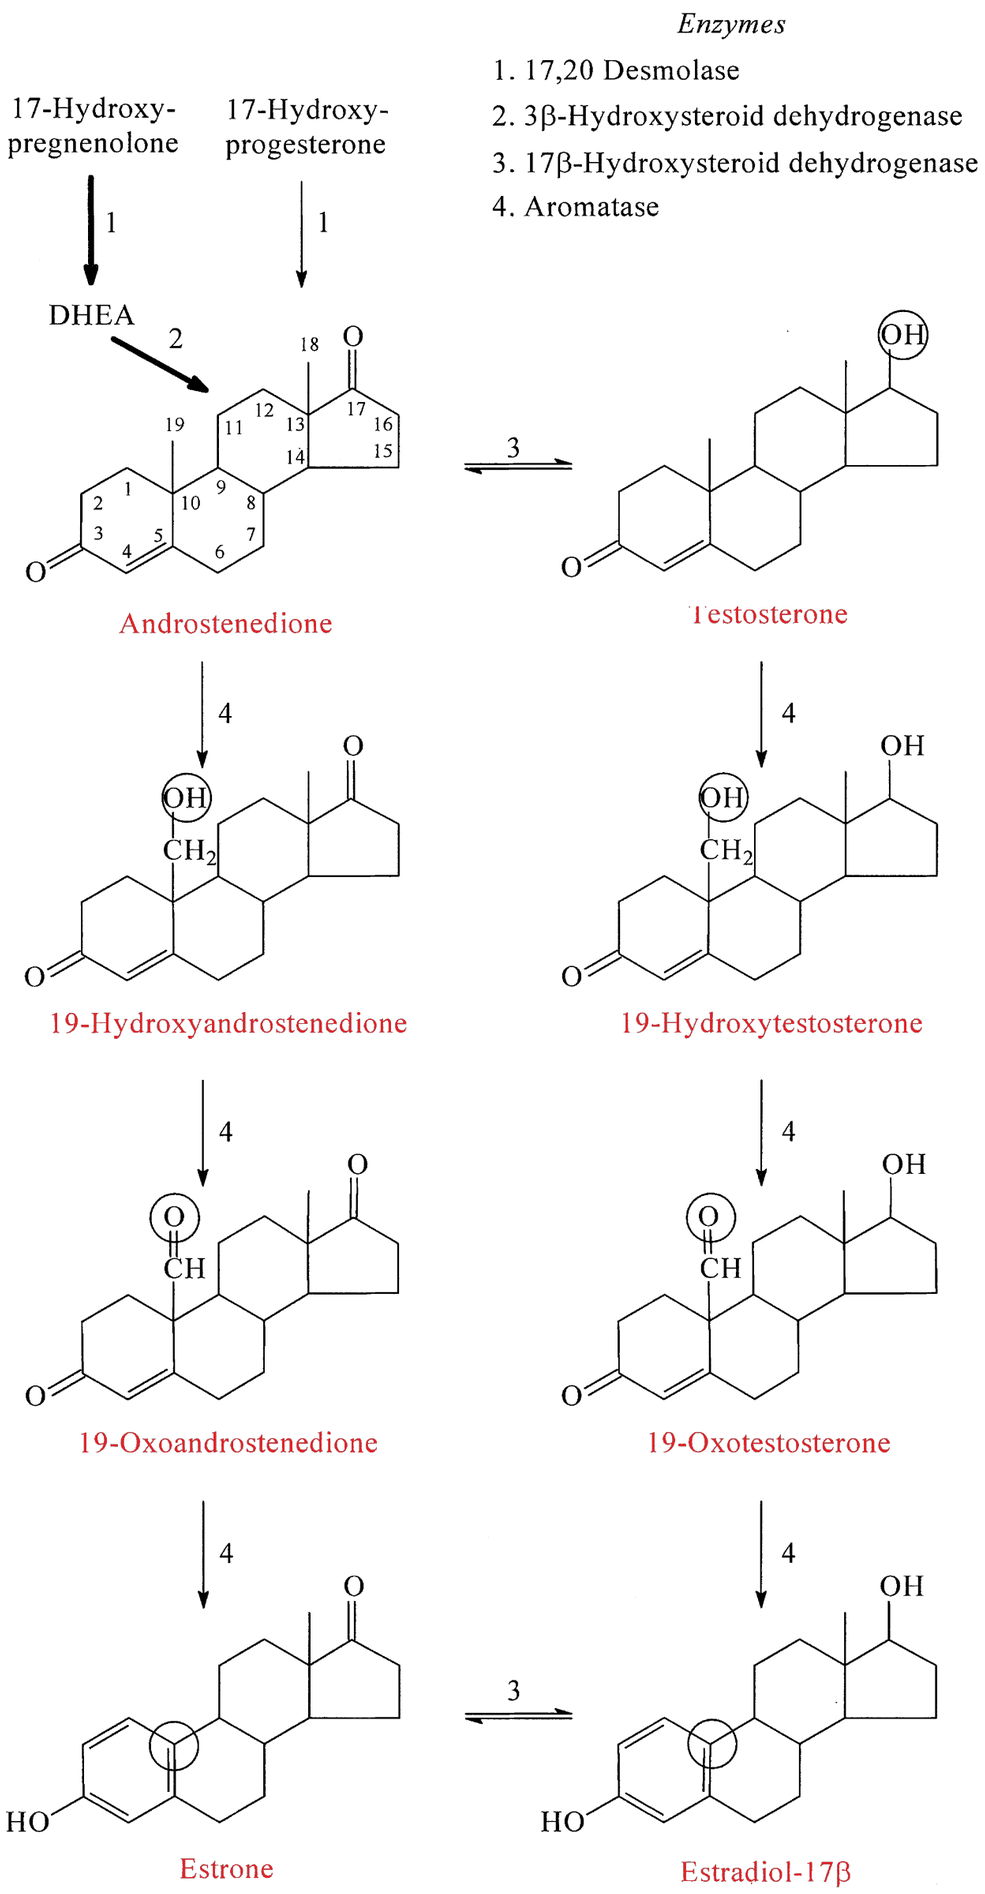

Figure 43-8 Biosynthesis of estrogens. Heavy arrows indicate the Δ5-3β-hydroxy pathway. The circled area represents the site of chemical change. See Figure 43-4 for early synthetic steps.

ones. In pregnant women, the major source of estrogens is the placenta, whereas in nonpregnant women, the ovaries are the main site of synthesis.[3,13] In contrast to the microgram quantities secreted by nonpregnant women, the quantity of estrogens secreted during pregnancy increases to milligram amounts. The major estrogen secreted by the ovary is E_2, whereas the major product secreted by the placenta is E_3. E_3 is formed from plasma dehydroepiandrosterone sulfate (DHEAS) in the placenta. Except during pregnancy, measurements of E_3 have little clinical value because in nonpregnant women, E_3 is derived almost exclusively from E_2.

E_3 is the predominant hormone of late pregnancy. Maternal E_3 is almost entirely (≈90%) derived from fetal and placental sources. It is first detected during the ninth gestational week and gradually increases during the first and second trimesters. Plasma and salivary E_3 concentrations peak approximately 3 to 5 weeks before labor and delivery. Measurements of (1) unconjugated E_3,[8] (2) α-fetoprotein, (3) hCG, and (4) **inhibin A** are commonly used as part of the "quad" maternal screens for fetuses with Down syndrome (see Chapter 44). On average, unconjugated E_3 is 0.72 times less than normal (reference interval at 16 weeks: 0.30 to 1.50 μg/L) when fetal Down syndrome is present.

Estrogen Transport in Blood

More than 97% of circulating E_2 is bound to plasma proteins. It is bound specifically and with high affinity to SHBG, and nonspecifically to albumin. SHBG concentrations are increased by estrogens and therefore are higher in women than in men. They are also increased during (1) pregnancy, (2) oral contraceptive use, (3) hyperthyroidism, and (4) administration of certain antiepileptic drugs, such as phenytoin. SHBG concentrations may decrease in hypothyroidism, obesity, or androgen excess. Only 2% to 3% of total E_2 circulates in free form. In contrast, E_1 and estrone sulfate circulate bound almost exclusively to albumin. As with testosterone, both free and albumin-bound fractions of E_2 are thought to be biologically available, but measurement of this fraction has not been shown to be clinically important.

Metabolism

Typically, E_2 is converted to E_1 by the reversible oxidation of the C-17 β-hydroxy group. E_1 is further oxidized along two pathways leading to formation of (1) catechol estrogens, and (2) E_3 (Figure 43-9). The direction of E_1 metabolism is affected by the pathophysiologic state. For example, obesity and hypothyroidism are associated with an increase in E_3 formation, whereas low body weight and hyperthyroidism are associated with formation of catechol estrogens.[3] Although assays for catechol estrogen measurement are available, they have no known current clinical value.

Progesterone

Progesterone, similar to the estrogens, is a female sex hormone. In conjunction with estrogens, it helps to regulate the accessory organs during the menstrual cycle.[4,12] This hormone is especially important in preparing the uterus for implantation of the blastocyst and in maintaining pregnancy. In nonpregnant women, progesterone is secreted mainly by the corpus luteum. During pregnancy, the placenta becomes the major source of this hormone. Minor sources are the adrenal cortex in both sexes and the testes in men.

Chemistry

The structural formula and metabolism of progesterone (pregn-4-ene-3,20-dione), a C_{21} compound, are shown in Figure 43-10. Like corticosteroids and testosterone, progesterone contains a keto group (at C-3) and a double bond between C-4 and C-5 (Δ^4); these structural characteristics are essential for **progestational** activity.

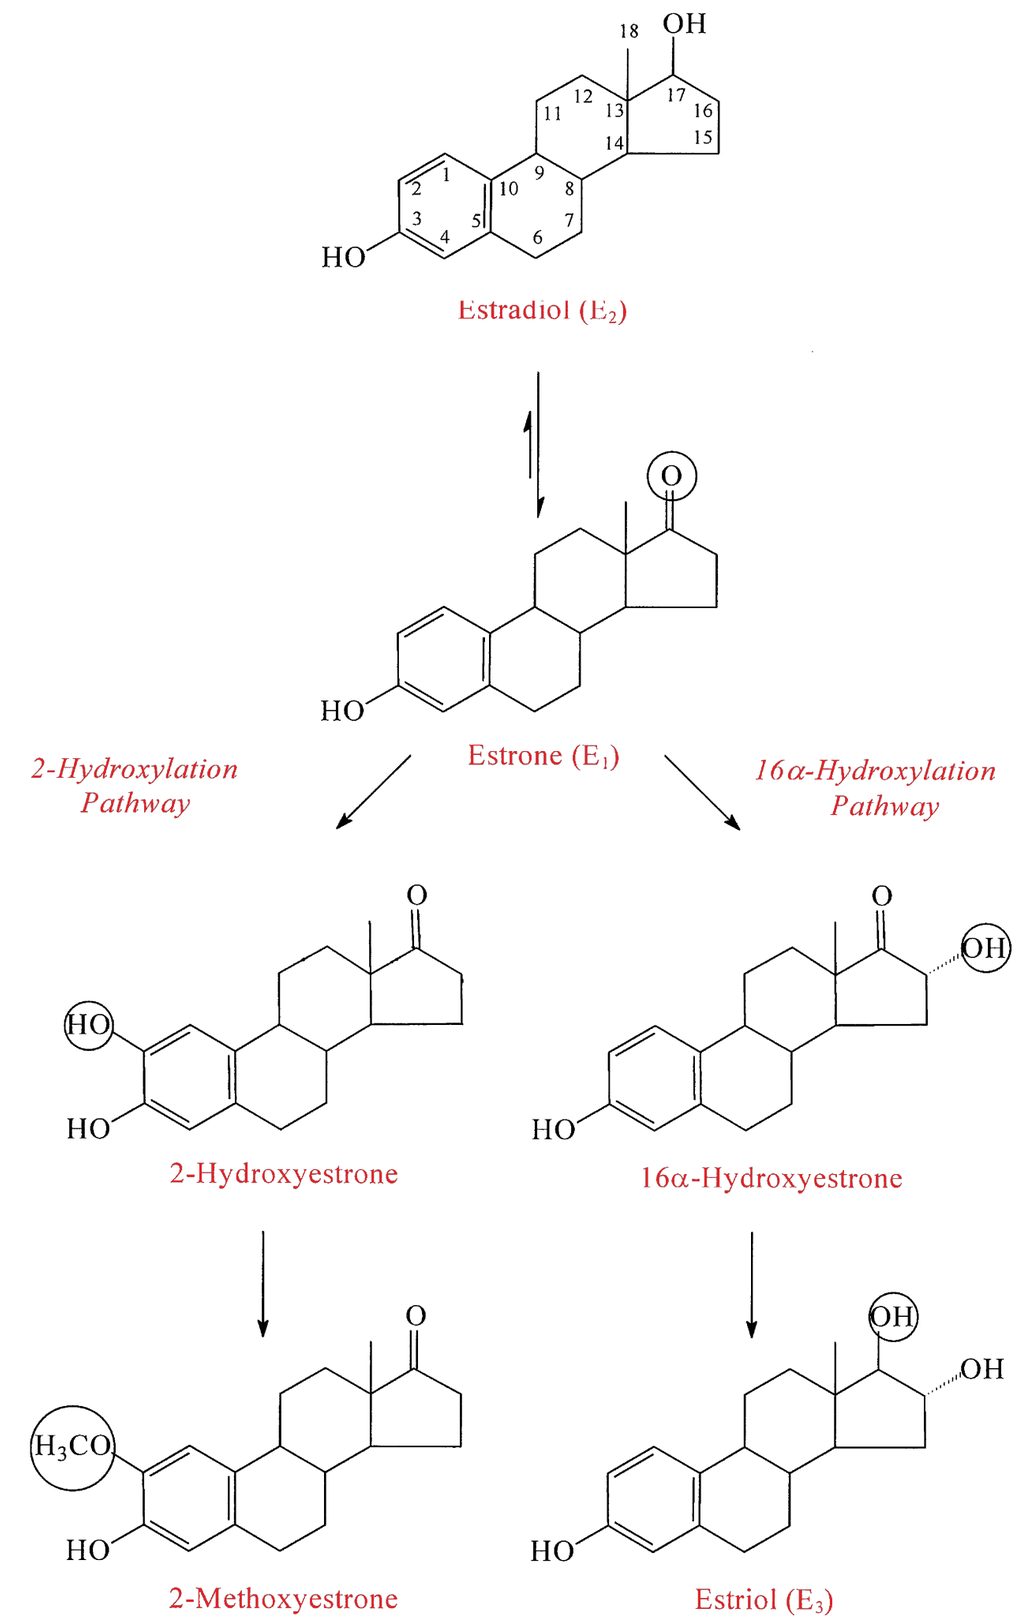

Figure 43-9 Main pathways of estradiol (E2) metabolism in humans. The circled area represents the site of chemical change.

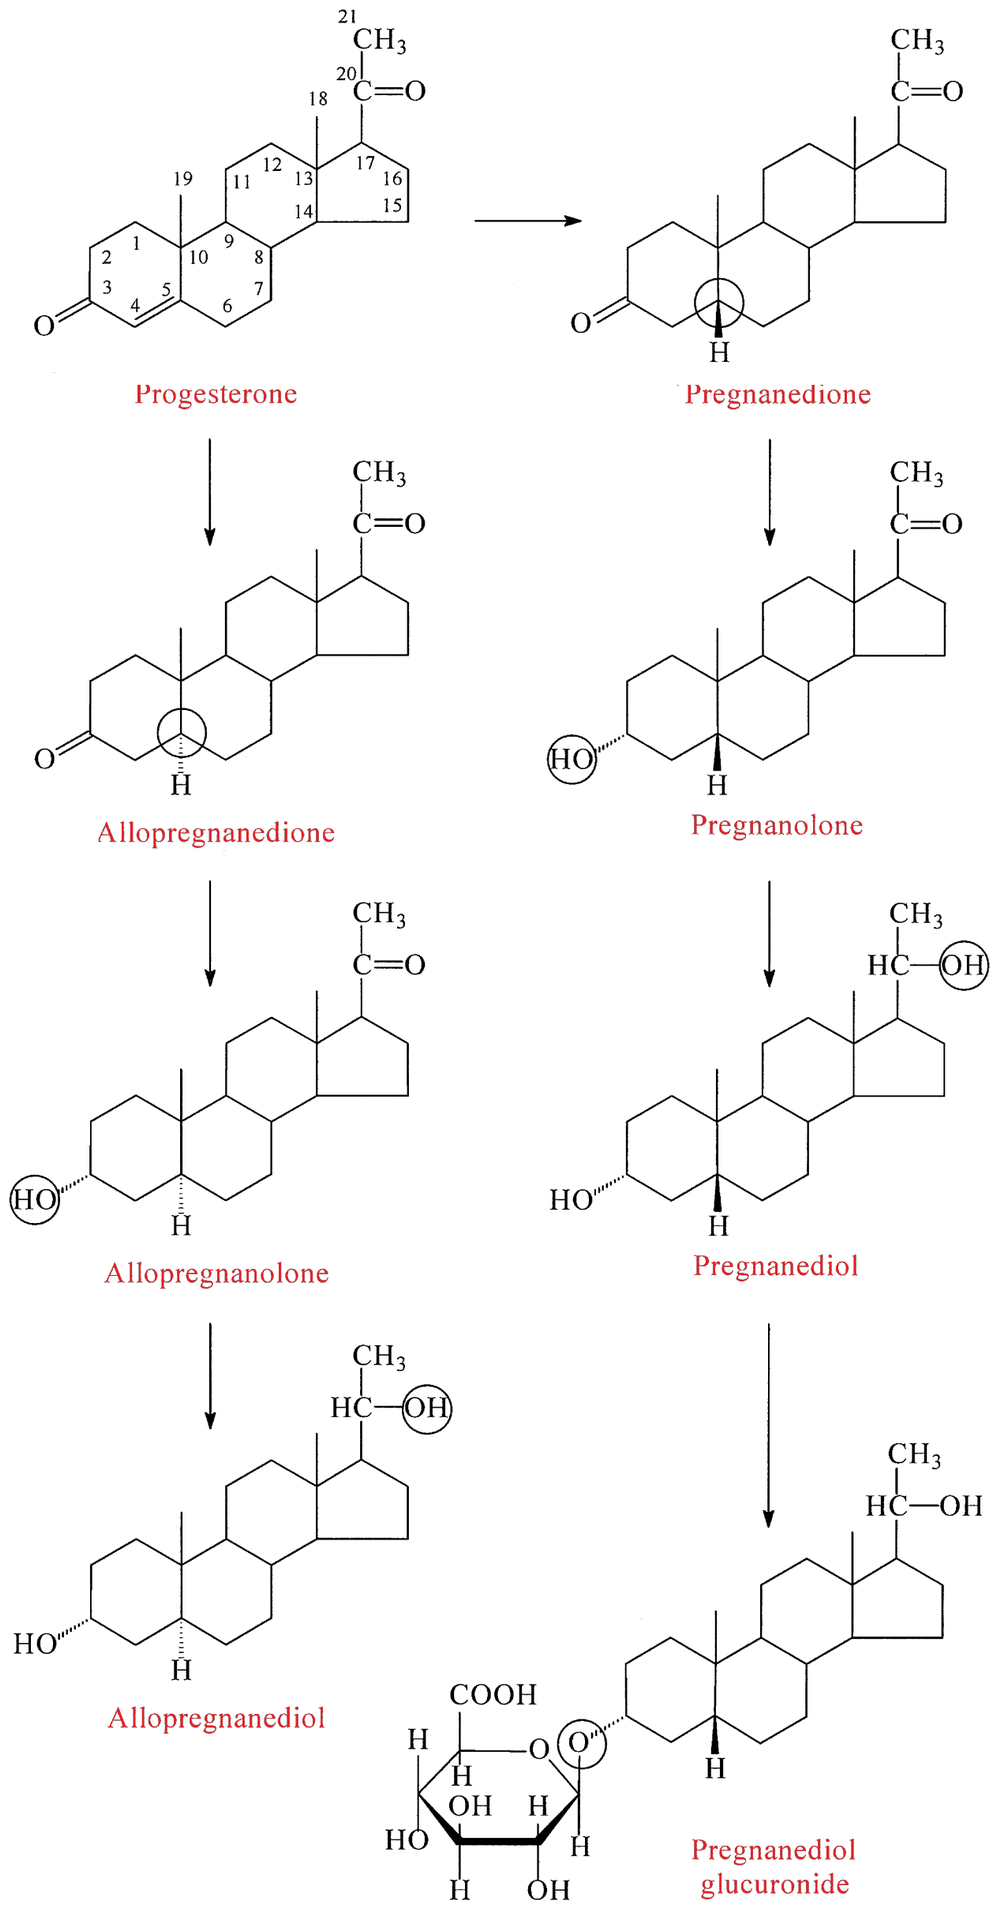

Figure 43-10 Metabolism of progesterone. The circled area represents the site of chemical change.

Biosynthesis

Biosynthesis of progesterone in ovarian tissues follows the same path from acetate to cholesterol through pregnenolone as it does in the adrenal cortex (see Chapter 41).[3,13] Initiation and control of luteal secretion of progesterone are regulated by LH and FSH.

Transport

Progesterone does not have a specific plasma-binding protein but, similar to cortisol, is bound by corticosteroid-binding globulin. Reported concentrations for plasma free progesterone vary from 2% to 10% of total concentration, and the percentage of unbound progesterone remains constant throughout the normal menstrual cycle.

Metabolism

Reduction and conjugation are important metabolic events leading to the inactivation of progesterone (Figure 43-10). Metabolites of progesterone are classified into groups based on the degree of reduction. T ey include (1) pregnanediones, (2) pregnanolones, and (3) pregnanediols. Reduced metabolites are eventually conjugated with glucuronic acid and excreted as water-soluble glucuronides.

Female Reproductive Development

Reproductive development begins with (1) anatomy during the fetal period, (2) a postnatal period of adaptation to reduced maternal sex steroids, and (3) finishes with sexual maturation during puberty.

Fetal Period

In the genotypic female, lack of testosterone and anti-Müllerian hormone result in the formation of the female reproductive tract. Gonadotropin activity in utero is suppressed because of high concentrations of circulating estrogens derived from the mother.

Postnatal Period

When the placenta separates, concentrations of fetal sex steroids drop abruptly. Serum E_2 in neonates decreases to basal concentrations within 5 to 7 days after birth and persists at this concentration until puberty. The negative feedback action of steroids is now removed, and gonadotropins are released. Postnatal peaks of LH and FSH are measurable for a few months after birth, peaking at 2 to 5 months and then dropping to basal concentrations. During childhood, circulating concentrations of sex steroids and gonadotropins are relatively low and are similar for both sexes.

Puberty

The transition from sexual immaturity appears to begin with diminished sensitivity of the pituitary gland or hypothalamus, or both, to the negative feedback effect of sex steroids. As puberty approaches, nocturnal secretion of gonadotropins occurs. Concentrations for (1) LH, (2) FSH, and (3) gonadal steroids rise gradually over several years before stabilizing at adult concentrations when full sexual maturity is reached. In girls, puberty is considered precocious if onset of pubertal development (secondary sex characteristics) occurs before the age of 8 years, and delayed if no development has occurred by the age of 13 years, or if **menarche** has not occurred by age 16.5 years. The median age of menarche in the United States is 12.43 years. Adrenarche precedes puberty by a few years. In girls, the rise in concentrations of (1) DHEA, (2) DHEAS, and (3) androstenedione begins at age 6 to 7 years. This is rise in adrenal androgen concentrations lasts until late puberty. In girls, puberty is associated with elevations in estrogen secretion by the ovary in response to gonadotropin concentrations that increase in response to GnRH.

Normal Menstrual Cycle

During a normal menstrual cycle, a closely coordinated interplay of feedback effects occurs between the (1) hypothalamus, (2) the anterior lobe of the pituitary gland, and (3) the ovaries. In addition, cyclic hormone changes lead to functional and structural changes in the (1) ovaries, (2) uterus, (3) cervix, and (4) vagina.

Phases

The menstrual cycle is measured beginning on day 1 as the first day of menstrual bleeding. Each cycle consists of a (1) follicular phase followed by (2) ovulation and then a (3) luteal phase.

Follicular Phase. The follicular phase begins with the initiation of follicular growth, begins during the last few days of the previous luteal phase and terminates at ovulation. During the early part of the follicular phase, concentrations of FSH are elevated, but they decline up until ovulation (Figure 43-5).[3] LH secretion begins to increase around the middle of the follicular phase. Just before ovulation, estrogen secretion by the follicle increases dramatically; this positively stimulates the hypothalamus and triggers the **LH surge**. The LH surge is a reliable predictor of ovulation with onset of the surge for 90% of women occurring 16 to 58 hours before, and the peak occurring 3 to 36 hours before, ovulation.[3] Ovulation occurs around day 14 of the menstrual cycle.

Ovulation. Ovulation occurs around day 14 of the menstrual cycle.

Luteal Phase. The luteal phase occurs in the last half of the cycle and is characterized by increasing production of progesterone and estrogen from the corpus luteum with consequent gradual lowering of LH and FSH concentrations. The concentration of progesterone reaches a peak at about 8 days post ovulation. If ovulation does not occur, the corpus luteum fails to form, and a cyclic rise in the concentration of progesterone is subnormal. If ovulation, fertilization and implantation occur, hCG maintains the corpus luteum and the concentration of progesterone continues to increase. In the absence of conception, the corpus luteum resolves, resulting in a decrease in estrogen and progesterone concentrations and a breakdown of the endometrium.

Role of Individual Hormones

The major hormones that influence the control and effects of the normal menstrual cycle include (1) GnRH, (2) FSH, (3) LH, (4) E_2, and (5) progesterone (Figure 43-6).

Gonadotropin-Releasing Hormone. GnRH triggers the LH surge that precedes ovulation.[3,7,13] There appear to be two separate feedback centers in the hypothalamus: (1) a tonic negative feedback center, and (2) a cyclic positive feedback center. Low concentrations of E_2, such as those that are present during the follicular phase, affect the negative feedback center, whereas high concentrations of E_2, such as those seen just before the midcycle LH peak, trigger the positive feedback center. Progesterone, in combination with estrogen, affects the negative feedback center in the luteal phase.

Follicle-Stimulating Hormone. A few days before day 1 of the cycle, FSH shows a slight but important peak (Figure 43-5). This is peak in FSH initiates the growth and maturation of a cohort of ovarian follicles.[3,7,13] LH and FSH release is pulsatile throughout the cycle. As estrogen is released from the growing follicles, FSH concentrations fall again and remain low through the follicular phase. By days 5 to 7, a single follicle is selected for further growth. The effect of FSH on the maturing follicle is increased through E_2-induced changes in FSH receptors. FSH, aided by E_2, acts on the cells of the follicle to increase the responsiveness of LH receptors by the time of the midcycle surge. FSH and LH receptors respond with an increase in their number or in their affinity for corresponding gonadotropin. A rise in FSH at midcycle is triggered by progesterone. During the luteal phase, FSH is suppressed by negative feedback from E_2 until a lesser FSH peak, occurring near the end of the cycle, starts off the follicular maturation of the next cycle.

Luteinizing Hormone. LH secretion is suppressed in the follicular phase by negative feedback from E_2.[7,13] As E_2 production by the developing follicle increases, the effect of E_2 on the positive feedback center becomes important. Increasing release of GnRH from the hypothalamus and increasing the sensitivity of the anterior lobe of the pituitary gland to it lead to the midcycle surge of LH. Ovarian follicle receptors for LH, sensitized by FSH and E_2, transmit the stimulus to

enhance differentiation of the theca cell and production of progesterone by the developing corpus luteum. LH production is suppressed during the luteal phase by negative feedback from progesterone combined with E_2.

Estradiol. E_2 production by the ovary decreases near the end of a cycle but begins to increase again under the influence of FSH (Figure 43-5).[3,7,13] E_2 enhances the FSH effect on a maturing follicle through changes in FSH receptors of the follicular cells, but it suppresses pituitary FSH and LH release during the follicular phase through negative feedback. Before the mid–follicular phase, estrogen concentrations are less than 50 pg/mL, but they increase rapidly as the follicle matures. E_2 production increases, reaching a midcycle peak at between 250 and 500 pg/mL. E_2 concentrations decrease abruptly after ovulation but increase again as the corpus luteum is formed, reaching concentrations of approximately 125 pg/mL during the luteal phase. Progesterone produced by the corpus luteum, combined with E_2, exerts a negative effect on the hypothalamus and anterior lobe of the pituitary gland. As a result, LH and FSH secretion is suppressed again during the luteal phase. E_2 is essential for the development of proliferative endometrium and is synergistic with progesterone for the development of changes in the endometrium that initiate shedding; the decrease in negative feedback from E_2 on the anterior lobe of the pituitary gland triggers the FSH surge that begins the development of an ovarian follicle for the next cycle.[3]

Progesterone. Progesterone is not produced in significant amounts until after the midcycle LH-surge and ovulation. LH enhances theca cell differentiation and progesterone production, which increase by a factor of 10 to 20 to a maximum about 8 days after the midcycle peak of LH. Progesterone is thought to stimulate the ovulatory peak of FSH and to promote the growth of secretory endometrium, which is necessary for implantation of the fertilized ovum.[3]

Ovulation

An intricate interplay of endocrine events contributes to follicular maturation. How an individual follicle is selected each menstrual cycle for maturation is unknown; however, the late-cycle peak in FSH concentration is likely important in this process. Once a follicle has been stimulated, E_2 production causes that specific follicle to be more receptive to effects of FSH. After ovulation, LH is suppressed by progesterone and E_2, but the effect of LH on the corpus luteum is increased.[7,13] In the event of a successful fertilization and implantation, corpus luteum function is sustained by hCG produced by trophoblastic cells of the developing embryo with high molecular homology to LH, and it is capable of binding and stimulating LH receptors. Otherwise, the declining concentration of E_2 leads to regression of the corpus luteum and to the late-cycle FSH peak that starts the process again.

Menopause

Menopause begins with the ovaries failing to produce adequate amounts of estrogen and inhibin; as a result, gonadotropin production is increased in a continued attempt to stimulate the ovary. The mean age of menopause in the United States is 51 years but varies considerably.[3,6] Ovarian failure may occur at any age, but menopause before age 40 years is considered premature.[6]

Hormonal changes begin about 5 years before the actual menopause, as the response of the ovary to gonadotropins begins to decrease and menstrual cycles become increasingly irregular. The term perimenopausal refers to the time interval from onset of these menstrual irregularities to menopause itself. This transition phase will last from 2 to 8 years.[6] At this time, FSH concentrations increase and E_2 concentrations decrease, whereas LH and progesterone concentrations remain unchanged, indicating that menstrual cycles are ovulatory. The decrease in estrogen concentrations gives rise to vasomotor instability and "hot flashes."

After menopause, the ovary continues to produce androgens, particularly testosterone and androstenedione, as a result of increased LH concentrations. In addition, the adrenal gland continues to secrete androgens. The resulting decrease in the estrogen/androgen ratio causes the **hirsutism** often seen in postmenopausal women.[1] Prolonged estrogen deficiency results in increased resorption and bone remodeling, leading to accelerated bone loss and osteoporosis in postmenopausal women.

It is important to note that perimenopausal and postmenopausal women secrete pituitary hCG.[5] Serum concentrations generally are low (<13 IU/L), but positive hCG results often causes confusion and delays important diagnostic tests or treatments. Pituitary versus placental hCG has been confirmed by measuring serum FSH (concentrations of FSH >45 IU/L are consistent with menopause and make pregnancy unlikely) or by 2 weeks of hormone replacement therapy (hormone replacement therapy should decrease LH, FSH, and hCG concentrations).[5]

Female Reproductive Abnormalities

A wide variety of abnormalities affect the female reproductive system and have been classified in a variety of manners. For the purposes of this chapter, they have been divided into categories of (1) **pseudohermaphroditism**, (2) precocious puberty, (3) irregular **menses**, and (4) menopause. **Infertility** from the male and female perspective is discussed in a separate section later in the chapter.

Female Pseudohermaphroditism

The female pseudohermaphrodite is an individual who is genetically female, but whose phenotypic characteristics are, to varying degrees, male. In neonates with a 46,XX karyotype and ambiguous genitalia, **congenital adrenal hyperplasia (CAH)** should be considered. CAH is a family of autosomal recessive disorders of adrenal steroidogenesis (see Chapter 41). Each disorder has a specific pattern of hormonal abnormalities resulting in deficiency or excess of androgens. Only deficiencies of 21-hydroxylase and 11β-hydroxylase enzymes are predominantly virilizing disorders. Deficiency of 3β-hydroxysteroid dehydrogenase is rare, but when it occurs, affected girls may exhibit **virilization**.

Diagnosis of **21-hydroxylase deficiency** is made in infants and children with excess excretion of urinary 17-KS and pregnanetriol and elevated concentrations of plasma 17-hydroxyprogesterone and androstenedione. Elevation of 17-hydroxyprogesterone concentrations in early infancy (>3000 ng/dL) confirms the diagnosis of this disorder.

An **11β-hydroxylase deficiency** is confirmed by finding (1) elevated plasma concentrations of 11–deoxycortisol and deoxycorticosterone, (2) increased concentrations of their metabolites in urine, and (3) their suppression by glucocorticoid therapy. Plasma renin activity and aldosterone concentrations are low in this deficiency.

Elevated plasma concentrations of (1) 17-hydroxypregnenolone, (2) DHEA, and (3) DHEAS are found in patients with **3β-hydroxysteroid dehydrogenase deficiency**. T e ratio of 17-hydroxypregnenolone to 17-hydroxyprogesterone is strikingly elevated in these patients.

Precocious Puberty

Precocious puberty is the development of secondary sexual characteristics in girls younger than 8 years old and boys younger than 9 years old. Early puberty is manifested by the appearance of secondary sexual characteristics, such as (1) premature thelarche (premature breast development), (2) premature adrenarche (premature sexual hair development), or (3) phallic enlargement. When presented as isolated cases, these secondary sexual characteristics are not considered to be pathologic, as none progresses to full-blown puberty, nor are they associated with increased rates of bone growth and maturation. However, if a child has at least two signs of puberty and also demonstrates increased rates of bone growth and maturation, the many causes of true precocious puberty must be considered.[4]

Precocious puberty has been classified as GnRH dependent or independent. GnRH-dependent precocious puberty (also called central precocious puberty) is due to precocious activation of the hypothalamic-pituitary-gonadal axis. **Pseudoprecocious puberty** (also called GnRH-independent precocious puberty) refers to precocious sex steroid secretion that is independent of pituitary gonadotropin release. CAHs are a common cause of pseudoprecocious puberty. Other causes include tumors of the (1) adrenal gland, (2) ovaries, and (3) testes that secrete androgens or estrogens.

Diagnosis of precocious puberty is based on (1) clinical presentation, (2) a thorough pubertal history, (3) bone age determinations, and (4) laboratory tests performed to assess gonadotropin concentrations and response to exogenous GnRH. T e GnRH stimulation test is the gold standard for diagnosis of GnRH-dependent precocious puberty. Pubertal responses of LH and FSH to GnRH stimulation are considered diagnostic of precocious puberty when chronological age is inappropriate for the hormone response. T e GnRH stimulation test is also used to monitor the effectiveness of GnRH agonist therapy. Typically, an IV bolus of exogenous GnRH is administered followed by a single measurement (at 40 to 45 minutes) or serial measurements of LH and FSH concentrations.

Breast Cancer—Effect of Estrogens

Suspicions of estrogen-based causes in the development of human breast cancer stem from epidemiologic and experimental observations.[11] Ovarian estrogen has been assumed to be the causative factor because administration of estrogen negates the protective effects of early oophorectomy (surgical removal of an ovary or ovaries). Moreover, treatment of men with estrogen for prostatic cancer or after transsexual operations is associated with increased risk of breast cancer. Low risk for breast cancer has consistently been connected with high parity. Increased risk is associated with early menarche, late (>30 years of age) first full-term pregnancy, and late menopause. Pregnancy occurring before age 25 to 30 years has a protective effect.

Cytoplasmic estrogen receptors are important prognostic indicators that are routinely measured in samples of breast tissue after surgical removal of the tumor. Sixty percent of patients with carcinoma of the breast have tumors that are estrogen receptor positive. T e greater the estrogen receptor content of the tumor, the higher is the response rate to endocrine therapy and the lower is the incidence of recurrence.

Irregular Menses

Healthy women display considerable variation in cycle length ranging from 25 to 30 days (28 days on average). **Amenorrhea,** the absence of menstrual bleeding, is traditionally categorized as (1) primary (women who have never menstruated) or (2) secondary (women in whom menstruation is present for a variable time and then ceases). Amenorrhea is a relatively common disorder with an estimated prevalence of 5%.

Primary Amenorrhea

Primary amenorrhea is defined as failure to establish spontaneous periodic menstruation by the age of 16 years regardless of whether secondary sex characteristics have developed. About 40% of phenotypic females who have primary amenorrhea (nearly always associated with absence of development of secondary sex characteristics) have **Turner syndrome** (45,X karyotype) or **pure gonadal dysgenesis** (46,XX or XY karyotype).[3] **Müllerian duct agenesis** or dysgenesis with absence of the vagina or uterus is the second most common manifestation, and the third most common is AIS (AR deficiency) and normal or elevated plasma testosterone concentrations if the patient is past puberty and is karyotype XY.

T e differential diagnosis of primary and secondary amenorrhea is shown in Table 43-1. When puberty is delayed in a girl, plasma concentrations of serum gonadotropins are measured. Low concentrations may indicate pituitary failure, whereas concentrations elevated into the postmenopausal interval indicate definite gonadal failure. In the latter case, chromosome studies are indicated. In the former case, pituitary function testing and radiography may be helpful. Patients with short stature without Turner syndrome but with primary amenorrhea may have multiple deficiencies of pituitary hormone secretion. In these patients, a craniopharyngioma or pituitary tumor should be suspected.

T e diagnosis of 17α-hydroxylase deficiency is made when the concentration of (1) serum progesterone is greater than

3 ng/mL; (2) 17α-hydroxyprogesterone is less than 0.2 ng/mL; (3) aldosterone is low; and (4) 11-deoxycorticosterone is elevated. Plasma concentrations of (1) 11-deoxycortisol, (2) testosterone, (3) E_2, and (4) DHEAS are also low. The diagnosis is made with an adrenocorticotropic hormone (ACTH) stimulation test in which baseline concentrations of progesterone and 17α-hydroxyprogesterone are measured first, followed by administration of 0.25 mg ACTH. Diagnosis is confirmed if serum concentrations of progesterone are significantly increased and 17α-hydroxyprogesterone concentrations are unchanged at 60 minutes after ACTH administration.

Secondary Amenorrhea

Secondary amenorrhea is defined as absence of periodic menstruation for at least 6 months in women who have previously experienced menses. With few exceptions, the causes of primary and secondary amenorrhea overlap (Box 43-2). Pregnancy, the most common cause of secondary amenorrhea, must be considered first and ruled out. Elevated concentrations of prolactin—iatrogenic or induced by a prolactin-secreting tumor—can result in oligomenorrhea or amenorrhea. It is thought that hyperprolactinemia inhibits the release of LH and FSH. Both hyperthyroidism and hypothyroidism are associated with a variety of menstrual disorders because of their effects on metabolism and inter-conversion of androgens and estrogens. In practice, it is helpful to separate patients with secondary amenorrhea into those with and without signs of hirsutism and androgen excess.

Assessment of women with secondary amenorrhea begins with a careful history that includes a complete description of menstrual patterns. In addition, the patient should be evaluated for (1) galactorrhea, (2) hot flashes, (3) abnormalities of thyroid size and function, (4) hirsutism,[1] (5) cushingoid appearance, (6) abdominal or pelvic masses, (7) pelvic or uterine trauma, (8) clitoral enlargement, (9) medications prescribed, (10) nutritional history, (11) patterns of exercise, (12) previous contraceptive use, (13) weight changes, (14) stress, (15) chronic disease, (16) visual field defects, and (17) evidence of malnutrition. Serum or urine hCG should be measured to rule out pregnancy. Because both hypothyroidism and hyperprolactinemia have been known to cause amenorrhea, they are easily excluded by measuring concentrations of serum TSH and prolactin.

A 24-hour urine cortisol or an overnight dexamethasone suppression test is performed in those patients suspected of having Cushing syndrome (see Chapter 41). A GnRH stimulation test with measurement of LH and FSH concentrations in those patients with gonadotropin deficiency assists in differentiating hypothalamic disease from pituitary disease.

Oligomenorrhea

Oligomenorrhea is infrequent menstruation that occurs fewer than nine times per year.

BOX 43-2 Causes of Amenorrhea

Primary Amenorrhea
Lower tract defects
- Vaginal aplasia
- Imperforate hymen
- Congenital vaginal atresia

Uterine disorders
- Congenital absence of the uterus
- Endometritis
- Müllerian agenesis (Mayer-Rokitansky-Kuster-Hauser syndrome)

Ovarian disorders
- XO gonadal and X dysgenesis and variants
- XX gonadal dysgenesis
- Turner syndrome
- Androgen insensitivity syndrome (AIS)
- 17-Hydroxylase deficiency of the ovaries and adrenal glands
- Autoimmune oophoritis
- Resistant ovary syndrome
- Polycystic ovary syndrome (PCOS)

Adrenal disorders (congenital adrenal hyperplasia [CAH])
Thyroid disorders (hypothyroidism)
Pituitary-hypothalamic disorders
- Hypopituitarism
- Constitutional delay in the onset of menses (physiologic)
- Nutritional disorders
- Kallmann syndrome

Secondary Amenorrhea
Pregnancy/lactation
Uterine disorders
- Post-traumatic uterine synechiae (Asherman syndrome)
- Progestational agents

Ovarian disorders
- Polycystic ovary syndrome (PCOS) (hypothalamic)
- Ovarian tumor
- Primary ovarian insufficiency (POI) (idiopathic, autoimmune, chemotherapy, radiation, injury)
- Antimetabolite therapy

Adrenal disorders
- Late-onset adrenal hyperplasia
- Cushing syndrome
- Virilizing adrenal tumors
- Adrenocorticoid insufficiency

Thyroid disorders
- Hypothyroidism
- Hyperthyroidism

Pituitary disorders
- Acquired hypopituitarism (trauma, tumor, Sheehan syndrome, lymphocytic hypophysitis)
- Physiologic or pathologic hyperprolactinemia

Hypothalamic disorders
- Tumor and infiltrative disease
- Nutritional disorders
- Hypophysitis
- Excessive exercise
- Stress

Iatrogenic
- Antipsychotics (phenothiazines, haloperidol, clozapine, pimozide)
- Antidepressants (tricyclics, monoamine oxidase inhibitors)
- Antihypertensives (calcium channel blockers, methyldopa, reserpine)
- Drugs with estrogenic activity (digitalis, flavonoids, marijuana, oral contraceptives)
- Drugs with ovarian toxicity (busulfan, chlorambucil, cisplatin, cyclophosphamide, fluorouracil)

Progesterone Challenge for Evaluating Amenorrhea

When the cause of amenorrhea is unclear after the initial assessment, relative estrogen status should be determined. Serum E_2 is measured, or a progesterone challenge may be performed.[3] Women with an estrogen-primed uterus have withdrawal vaginal bleeding after being administered oral progestin at concentrations of (1) 30 mg daily for 3 days, (2) 10 mg daily for 5 to 10 days, or (3) 100 to 200 mg of progesterone in oil given intramuscularly. If estrogen concentrations are adequate and the outflow tract is intact, menstrual bleeding should occur within a week of treatment. In patients with withdrawal bleeding, the plasma E_2 concentration is usually greater than 40 pg/mL. Measurement of serum E_2 is an alternative to the progesterone challenge but is not preferred because estrogen concentration fluctuates throughout the day, and withdrawal bleeding is an indication of a normal outflow tract. If bleeding fails to occur after progestin challenge, then additional laboratory tests are indicated, including measurement of LH and FSH to localize the problem to the (1) follicle, (2) pituitary, or (3) hypothalamus.

Androgen Excess

Amenorrhea due to androgen excess has been shown to be due to (1) adult-onset CAH, (2) corticotropin-dependent Cushing syndrome, or (3) **polycystic ovary syndrome (PCOS)**. Patients with androgen excess often will present with (1) acne, (2) obesity, and (3) variable degrees of excess hair on the (a) face, (b) chest, (c) abdomen, and (d) thighs. Some individuals with 21-hydroxylase deficiency do not manifest any developmental abnormalities or salt wasting, but they present with signs of androgen excess. This clinical syndrome, referred to as nonclassic, adult-onset, or late-onset CAH, may be clinically indistinguishable from PCOS.[2]

PCOS occurs in ≈4% of premenopausal women, and is clinically defined by **hyperandrogenism** with chronic anovulation in women with no other cause. This syndrome is characterized by (1) infertility, (2) hirsutism, (3) obesity, and (4) various menstrual disturbances ranging from amenorrhea to irregular vaginal bleeding (Table 43-2). Relatively low FSH and disproportionately high LH concentrations are common in PCOS. Serum androstenedione and testosterone concentrations (total and free concentrations) are elevated with mean concentrations 50% to 150% higher than normal.[3] PCOS patients have substantial estrogen production due to peripheral conversion of androgens to estrogens.

Hirsutism and Virilization[1]

Hirsutism is defined as excessive growth of terminal hair in women and children in a distribution similar to that occurring in postpubertal men. True hirsutism, which is androgen responsive, is distinguished from **hypertrichosis**, which

TABLE 43-2 Clinical Features of the Polycystic Ovary Syndrome*

Clinical Features	Frequency
Hirsutism	65
Acne	26
Obesity	37
Infertility	48
Amenorrhea	35
Oligomenorrhea	42
Regular menstrual cycle	20

*Data were compiled from three studies. Two used ultrasonography as the primary method of diagnosis, one used ovarian histology. Total N=1935.
Modified from Frank S. Polycystic ovary syndrome. N Engl J Med 1995;333:1435.

BOX 43-3 Causes of Hirsutism

Ovarian
Severe insulin resistance
Hyperthecosis, hilus cell or stromal cell hyperplasia
Androgen-producing ovarian tumor
Menopause

Adrenal
Classic congenital hyperplasia
- 21-Hydroxylase deficiency
- 11-Hydroxylase deficiency
- 3β-Hydroxysteroid dehydrogenase deficiency

Adult or attenuated adrenal hyperplasia
Androgen-producing adrenal tumor

Familial Hirsutism

Endocrine Disorders
Polycystic ovary syndrome (PCOS)
Hyperprolactinemia
Acromegaly
Cushing syndrome

Idiopathic Hirsutism (Includes Increased Skin Sensitivity to Androgens)

Iatrogenic
Androgens
Dilantin
Diazoxide
Minoxidil
Streptomycin
Cyclosporine
Danazol
Metyrapone
Phenothiazides
Progestagens (19-nonsteroid derivatives)

consists of excessive growth of vellus or non–androgen-responsive hair. The causes of hirsutism are listed in Box 43-3.

Virilization is characterized by (1) clitoral hypertrophy, (2) deepening of the voice, (3) temporal hair recession, (4) baldness, (5) increased libido, (6) decreased body fat, and (7) menstrual irregularities or amenorrhea. Hirsutism is usually associated with normal or slightly elevated serum androgens, whereas virilization is associated with marked increases in ovarian or adrenal androgen production.[3]

Important screening tests used in the evaluation of women for hirsutism and virilization are the measurement of serum total or free testosterone and DHEAS.[3] Increased concentrations of DHEAS suggest an adrenal origin of androgens, whereas increased concentrations of testosterone indicate an adrenal or ovarian source. Neoplastic disease is unlikely if the (1) serum testosterone concentration is less than 2 ng/mL, (2) DHEAS concentration is less than 700 μg/dL, or (3) 17-KS concentrations are less than 30 mg/d. Regardless of the source of excess androgen production, the androstanediol glucuronide concentration is elevated in more than 90% of women with hirsutism, because it is a marker of excessive DHT production in skin.

PCOS is primarily a clinical diagnosis, and few laboratory tests are needed. Given a history of androgen excess and chronic anovulation (usually since menarche), the only condition that needs to be excluded is 21-hydroxylase–deficient nonclassic CAH; this is achieved by measuring 17-hydroxyprogesterone (early morning; follicular phase). If the result is less than 2 ng/mL, nonclassic CAH is excluded. Serum testosterone measurement is not necessary if clear hirsutism is present. Testosterone concentrations greater than 60 ng/dL are consistent with PCOS. FSH concentrations are often disproportionately normal or low. Patients with PCOS usually have E_2 concentrations greater than 40 pg/mL and therefore experience withdrawal bleeding in response to a progestin challenge.

Morning plasma 17α-hydroxyprogesterone concentrations are measured to evaluate nonclassic or **late-onset 21-hydroxylase deficiency (NCAH)**. A concentration less than 200 ng/dL (6.1 nmol/L) excludes this diagnosis, and a concentration greater than 1500 ng/dL (30 nmol/L) in nonpregnant women is confirmatory. When basal concentrations between 200 and 1500 ng/dL are found, an ACTH stimulation test should be performed. NCAH typically responds with a 17α-hydroxyprogesterone concentration greater than 1500 ng/dL, and classic CAH has a response over 2000 ng/dL. Patients with attenuated forms of CAH usually have normal concentrations of FSH and LH. About one half have elevated testosterone and androstenedione concentrations. Most of these patients also have increased concentrations of DHEAS, and more than 90% have supranormal concentrations of androstanediol glucuronide.

Other Causitive Factors

Many other factors or conditions have been observed to cause secondary amenorrhea, including disorders of the (1) ovary, (2) uterus, (4) pituitary, and (5) hypothalamus, and (6) the use of drugs.

Disorders of the ovary, such as **primary ovarian insufficiency (POI)** (formerly referred to as premature ovarian failure [POF]) and loss of ovarian function, have been known to cause amenorrhea. POI has been defined as failure of ovarian estrogen production that occurs in a hypergonadotropic state at any age between menarche and 40 years.[3] Autoimmune disorders have been associated with 20% to 40% of cases of POI that result in destruction of the ovary and in amenorrhea.[3] Other causes for ovarian failure include (1) oophorectomy, (2) cystic degeneration, (3) trauma, (4) infection, (5) interference with blood

supply, (6) radiotherapy treatment, and (7) treatment with cytotoxic chemotherapeutic agents.

Hypothalamic dysfunction consists of those disorders that disrupt the frequency or amplitude of GnRH. Most commonly, disruption occurs in response to (1) psychological stress, (2) depression, (3) severe weight loss, (4) anorexia nervosa, or (5) strenuous exercise. A syndrome known as the **female athletic triad** has been described. T is syndrome is prevalent in women who exercise vigorously, and is associated with (1) amenorrhea, (2) disordered eating, and (3) osteoporosis. Many other factors or conditions have been observed to cause secondary amenorrhea, including disorders of the (1) ovary, (2) uterus, and (3) pituitary, and the (4) use of drugs.

Infertility

Infertility is defined as the inability to conceive after 1 year of unprotected intercourse.[15] It has been estimated that 93% of healthy couples practicing unprotected intercourse should expect to conceive within 1 year, and 100% will be successful within 2 years. Primary infertility refers to couples or patients who have had no previous successful pregnancies. Secondary infertility encompasses patients who have previously conceived, but are currently unable to conceive. T ese types of infertility generally share common causes.

Infertility problems often arise as a result of hormonal dysfunction of the hypothalamic-pituitary-gonadal axis. Measurements of peptide and steroid hormones in the serum are therefore essential aspects of the evaluation of infertility, and are the focus of this section.

Male Infertility

A list of the most common male infertility factors is given in Box 43-4. Laboratory evaluation of male infertility should begin with evaluation of semen, which should be followed by evaluation of endocrine parameters.

Evaluation of Semen

Semen analysis measures (1) ejaculate volume, (2) pH, (3) sperm count, (4) motility, (5) forward progression, and (6) morphology.[16] Semen should be analyzed within 1 hour after collection. Although semen analysis is not a test for infertility, it is considered the most important laboratory test in the evaluation of male fertility. Reference seminal fuid values provided by the World Health Organization (WHO) guidelines have helped establish limits of adequacy.[16] If semen analysis is normal, it is unlikely that other laboratory testing will be useful. If semen analysis is abnormal, it should be repeated in ≈6 weeks. Additional investigations may include measurement of **sperm protein SP-10** via immunoassay. SP-10 is **testis**-specific, arises within the acrosomal vesicle during spermatogenesis, and is associated with the acrosomal membranes and matrix of mature sperm. A version of the test is available to check the success of vasectomy.

Evaluation of Obstruction

Obstruction of the male reproductive tract results in male infertility, and analysis of specific semen parameters has proved a useful adjunct to physical examination in the evaluation of male reproductive tract obstruction. Testosterone produced after administration of hCG causes the (1) seminal vesicles, (2) epididymis, and (3) prostate to increase the volume of ejaculate. An appropriate increase in serum testosterone without change in the ejaculate volume may indicate mechanical blockage.

BOX 43-4 Male Infertility Factors

Endocrine Disorders
- Hypothalamic dysfunction (Kallmann syndrome)
- Pituitary failure (tumor, radiation, surgery)
- Hyperprolactinemia (drug, tumor)
- Exogenous androgens
- Thyroid disorders
- Adrenal hyperplasia
- Testicular failure

Anatomic
- Congenital absence of vas deferens
- Obstructed vas deferens
- Congenital abnormalities of ejaculatory system
- Varicocele
- Retrograde ejaculation

Abnormal Spermatogenesis
- Unexplained azoospermia
- Chromosomal abnormalities
- Mumps orchitis
- Cryptorchidism
- Chemical or radiation exposure

Abnormal Motility
- Absent cilia (Kartagener syndrome)
- Antibody formation

Psychosocial
- Unexplained impotence
- Decreased libido

Modified from Morell V. Basic infertility assessment. Primary Care 1997;24:195-204.

Evaluation of Endocrine Parameters

If severe oligospermia (low sperm count) or azoospermia (no measurable sperm in semen) is found, then measurement of (1) serum testosterone, (2) LH, and (3) FSH concentrations is warranted, with or without measurement of (4) prolactin and (5) TSH concentrations. Hyperprolactinemia is a cause of secondary testicular dysfunction. If hyperprolactinemia is found, it is imperative to check for hypothyroidism, because elevated TRH concentrations result in hyperprolactinemia. Pituitary adenomas and drugs, such as (1) anxiolytics, (2) antihypertensives, (3) serotonergics, and (4) histamine H_2 receptor antagonists also increase serum prolactin. Hyperthyroidism and hypothyroidism will alter spermatogenesis. Hyperthyroidism affects both pituitary and testicular function with alterations in the secretion of releasing hormones and increased conversion of androgens to estrogens.

Patients with borderline or suppressed testosterone concentrations are evaluated with an **hCG stimulation test.** With this test, an injection of 5000 IU hCG is administered intramuscularly following collection of a basal, early morning

testosterone sample. Serum testosterone is measured 72 hours later. Hypogonadal men show a depressed rise in testosterone concentration in response to this challenge. Doubling of testosterone concentration over baseline is consistent with normal Leydig cell function. Failure to increase testosterone concentrations to greater than 150 ng/dL indicates primary hypogonadism.

Hypergonadotropic Hypogonadism

Measurement of the concentration of FSH is indicated in men with sperm count lower than 5 to 10 million/mL. Elevated concentrations of FSH indicate (1) Sertoli cell dysfunction and, in azoospermic men, (2) primary germinal cell failure, (3) **Sertoli cell–only syndrome** (a condition resulting in sterility due to the absence of living sperm cells in the semen), or (4) genetic conditions, such as Klinefelter syndrome (47,XXY karyotype). Elevated FSH (>120 mIU/mL) in the setting of decreased testosterone (<200 ng/dL) and oligospermia indicate primary testicular failure.

Hypogonadotropic Hypogonadism

Decreased concentrations of testosterone (<200 ng/dL) and decreased concentrations of FSH (<10 mIU/mL) are suggestive of hypogonadotropic hypogonadism. Administering GnRH may help to distinguish between gonadal insufficiencies caused by pituitary versus hypothalamic dysfunction. One approach to this test involves the intravenous injection of 100 µg of GnRH with measurement of FSH and LH concentrations at 0, 30, 60, 120, and 180 minutes after injection. An increase in serum gonadotropins of 10 mIU/mL or more over baseline is normal. If little to no increase in gonadotropins is seen, pituitary disease is likely. Patients with hypothalamic disease demonstrate a delayed but significant increase of 7 mIU/mL or more within 180 minutes.

Female Infertility

Factors associated with common female infertility are listed in Box 43-5.

BOX 43-5 Female Infertility Factors

Ovarian or Hormonal Factors
- Metabolic disease
  - Thyroid
  - Liver
  - Obesity
  - Androgen excess
  - Polycystic ovary syndrome (PCOS)
- Hypergonadotropic hypogonadism
  - Menopause
  - Luteal phase deficiency
  - Gonadal dysgenesis
  - Primary ovarian insufficiency (POI) (autoimmune, cytotoxic, chemotherapy, radiation, tumor)
  - Resistant ovary syndrome
- Hypogonadotropic hypogonadism
  - Hyperprolactinemia (tumor, drugs)
  - Hypothalamic insufficiency (Kallmann syndrome)
  - Pituitary insufficiency (tumor, necrosis, thrombosis, stress, exercise, anorexia)

Tubal Factors
- Occlusion or scarring
- Salpingitis isthmica nodosa
- Infectious salpingitis

Cervical Factors
- Stenosis
- Inflammation or infection
- Abnormal mucous viscosity

Uterine Factors
- Leiomyomata
- Congenital malformation
- Adhesions
- Endometritis or abnormal endometrium

Psychosocial Factors
- Decreased libido
- Anorgasmia

Iatrogenic

Immunologic (antisperm antibodies)

Modified from Morell V. Basic infertility assessment. Primary Care 1997;24:195-204.

Evaluation of Female Infertility

The initial evaluation of female infertility includes a detailed history and physical examination. The physical examination should include evaluation of (1) the external genitalia and hair pattern (for signs of androgen excess including clitoromegaly, hirsutism, and virilization), (2) the pelvis (for masses, nodularity or tenderness), the (3) breasts (for signs of galactorrhea), (4) neurological findings (sense of smell and visual impairments), (5) the thyroid (for enlargement or nodules), and (6) body mass index. All abnormalities in the history and physical examination should be pursued. A thorough medical and surgical history is also necessary including an assessment of (1) the patient's gravidity and parity, (2) coital frequency, (3) duration of infertility, and (4) prior work up and treatment for infertility. Also, (1) history of sexually transmitted infections, (2) assessment of previous cervical cytologic and HPV testing and treatment, and (3) a menstrual history should be obtained. Concentrations of (1) TSH, (2) testosterone, and (3) prolactin should be measured if menstrual cycles are absent or irregular or if there are signs of galactorrhoea or thyroid abnormalities. Ovulation reserve testing as discussed below should be considered in cases where diminished ovarian reserve is suspected.

Evaluation of Ovulation

Currently, laboratory tests will not confirm ovum release. However, measurement of the concentration of mid-luteal plasma progesterone does indicate that a corpus luteum was formed. Other methods such as measurement of the LH surge (to predict ovulation) and basal body temperature (to detect a rise in progesterone) have been used to assess ovulation.

Clinical Utility of Progesterone Measurements. Measurement of serum progesterone concentration is the primary

assay used for the evaluation of ovulation. Beginning immediately after ovulation, serum progesterone concentrations rise and peak within 5 to 9 days during the mid-luteal phase (days 21 to 23). If ovulation does not occur, the corpus luteum fails to form, and the expected cyclic rise in progesterone concentration is subnormal. If pregnancy occurs, hCG maintains the corpus luteum, and progesterone production continues to rise. Mid-luteal progesterone concentrations greater than 3 ng/mL indicate that ovulation has taken place, although concentrations of 10 ng/mL or more are more common in conception cycles. Concentrations less than 10 ng/mL indicate the possibility of inadequate luteal phase progesterone production, or inappropriate timing of sample collection.[14]

Clinical Utility of Measurement of Basal Body Temperature. Basal body temperature charts have long been accepted as simple, cost-effective indicators of ovulation. Ovulation is associated with a rapid rise in body temperature (by 0.5 °F), which persists through the luteal phase. The rise in temperature is due to increased quantities of progesterone. However, similar to progesterone, the rise in body temperature is evident only retrospectively and therefore does not predict imminent ovulation in a way helpful for timing intercourse.

Clinical Utility of the Measurement of the Luteinizing Hormone Surge. LH appears in the urine just after the serum LH surge and 24 to 36 hours before ovulation. Measurement of LH does not confirm ovulation or provide insight into the cause of anovulation, but rather indicates when ovulation should occur and provides a guide with which to time intercourse. Home LH kits provide information as to the timing of ovulation, and may reduce stress and costs associated with infertility programs. These tests effectively predict ovulation in 70% of women.

Evaluation of Endocrine Parameters

Disorders of the (1) hypothalamus, (2) pituitary, and (3) ovary are endocrine causes of infertility in women.

Hypergonadotropic Hypogonadism

In women younger than 40 years, hypergonadotropic hypogonadism is indicated by repeatedly elevated basal FSH concentrations (>30 IU/L) or a single elevation of greater than 40 IU/L. These patients are hypoestrogenic (E_2 <20 IU/L) and do not respond to a progestin challenge because their endometrium is atrophic. Basal serum FSH has been used as an indicator of relative ovarian reserve.

Assessing Ovarian Reserve. Women in their mid to late 30s and early 40s with infertility constitute the largest portion of the total infertility population and are at increased risk for pregnancy loss. This reflects a diminished ovarian reserve as a result of follicular depletion and a decline in oocyte quality. As women age, serum FSH concentrations in the early follicular phase begin to increase.

A rise in basal FSH is an excellent indicator of ovarian aging. In general, day 3 FSH concentrations greater than 20 to 25 IU/L are considered to be elevated and associated with poor reproductive outcome. Concomitant measurement of serum E_2 concentration adds to the predictive power of an isolated FSH determination. Basal E_2 concentrations greater than 75 to 80 pg/mL are associated with poor response to ovarian stimulation and pregnancy outcome. The concentration of inhibin B has been used in conjunction with serum FSH and E_2 to assess ovarian function. Inhibin is produced by gonadal tissue and thus is thought to be a more direct marker of gonadal activity and ovarian reserve than pituitary hormones alone.

Hypogonadotropic Hypogonadism

In hypogonadotropic hypogonadism, serum E_2 concentrations are less than 40 pg/mL (110 pmol/L); therefore, there is no withdrawal bleeding with a progestin challenge. Quantities of LH (<10 IU/L) and FSH (<10 IU/L) are decreased. Hyperprolactinemia causes hypergonadotropic hypogonadic infertility. The upper limit of normal plasma prolactin in an amenorrheic, hypoestrogenic, nonpregnant woman is 400 to 500 mIU/mL (20 to 25 ng/mL). If estrogen status is normal, maximum prolactin concentrations vary from 600 to 800 mIU/mL (30 to 40 ng/mL). TSH should be measured to exclude hypothyroidism. Prolactin concentrations are elevated in patients with PCOS and those taking medications, such as (1) antidepressants, (2) cimetidine, and (3) methyldopa, and (4) in stressful conditions. Radiographic imaging of the pituitary is indicated to rule out pituitary adenoma or empty sella syndrome.

Analytical Methodology

Various methods are available for measurement of male and female reproductive and related hormones in body fluids. Reference intervals for many of these hormones are listed in Table 50-1 in Chapter 50.

Measurement of Total Testosterone in Blood

The circulating concentration of testosterone collectively includes a (1) non–protein-bound or "free" form, (2) weakly bound form, and (3) tightly bound form. The weakly bound form is associated with albumin and the tightly bound form with SHBG (also known as testosterone/E_2-binding globulin). The term total testosterone refers to a serum measurement that includes (1) free testosterone, (2) albumin-bound testosterone, and (3) SHBG-bound testosterone. Bioavailable testosterone includes circulating free testosterone and albumin-bound testosterone. Testosterone bound to SHBG is not biologically active, whereas the free form is available for target cells. Albumin-bound testosterone is also available to target tissue because testosterone dissociates from the albumin carrier and rapidly diffuses into target cells.

Methodology

Enzyme (nonisotopic) immunoassays and tandem mass spectrometry (MS/MS) are widely used techniques for measuring the concentration of circulating testosterone. Isotope-dilution gas chromatography mass spectrometry

(IDGC-MS) is the reference method for testosterone measurement,[3] and there is a candidate liquid chromatography-MS/MS method. For the measurement of testosterone in females and prepubertal subjects, mass spectrometry is the method of choice, as it is the only method that can accurately and precisely quantify testosterone concentrations below 5.2 nmol/L (150 ng/dL).[11]

Direct (no extraction required) immunoassay methods have been reported for the determination of testosterone in serum or plasma. In such methods, testosterone must be displaced from its binding proteins (albumin and SHBG). Methods used to release it from the endogenous binding proteins include use of (1) salicylates or surfactants, (2) chemicals that alter pH, (3) techniques to change temperature, and (4) competing steroids, such as E_1 or E_2.

Fully automated immunoassays incorporating analogs labeled with enzymes, and fluorescent- or chemiluminescent-signaling molecules are commercially available for routine use. For adult male patients, these assays have demonstrated acceptable precision and recovery, and agreement with GC-MS and RIA methods. However, the use of such assays for female and prepubertal subjects is contraindicated, and a mass spectrometry method is required.[12]

Regardless of the type of immunoassay used, almost all testosterone antisera show some degree of cross-reactivity with DHT (typically 3% to 5%), but show negligible cross-reactivity with other androgens. Assays that use antisera generated against the C-19 position give maximum analytical specificity with respect to endogenous steroids. However, cross-reactions with 19-norsteroids that are used in contraceptive preparations have caused a problem. In most clinical situations, estimation of testosterone without prior separation of DHT is permitted because plasma concentrations of DHT are only 10% to 20% of those for testosterone. Moreover, testosterone and DHT are the two most important androgens in the systemic circulation. Even when a method measures the concentrations of both of them, clinically useful information about the total androgen load still is obtained. However, if specific estimation of just testosterone concentration is required, then chromatographic separation of testosterone and DHT prior to analysis is usually necessary to obtain reliable immunoassay results.

Specimen Collection and Storage

Either serum or heparinized plasma is used to measure total or free testosterone. Testosterone is subject to a diurnal variation, reaching a peak concentration between 400 and 800. Therefore morning specimens are preferred. Specimens are stable for a week (men) or 3 days (women) refrigerated and for up to 1 year at −20 °C. Medications such as (1) steroid, (2) thyroid, (3) ACTH, (4) E_2, or (5) gonadotropin drugs should not be given for 48 hours before sample collection. Most assays are standardized for serum or heparinized plasma. Other anticoagulants, such as ethylenediaminetetraacetic acid (EDTA), may give different values. In certain RIA assays, presence of EDTA can cause a 10% decrease in total testosterone concentrations.

Comments

Knowledge of the SHBG concentration in serum can be very useful for interpreting blood concentrations of testosterone. Assays for measuring SHBG include (1) binding assays, in which the quantity of a radiolabeled androgen bound to SHBG is measured; and (2) specific immunoassays for the SHBG protein.

Measurement of Free and Weakly Bound Testosterone in Blood

Several methods are available for determining the concentrations of the free or bioavailable forms of testosterone in serum or plasma. These include methods that estimate the (1) free testosterone fraction by equilibrium dialysis or ultrafiltration, (2) free hormone using a direct ("analog tracer") immunoassay, (3) combined free and weakly bound ("bioavailable") testosterone fractions by selective precipitation of the tightly bound form, (4) androgen index using indices that reflect ratios of the testosterone pools, and (5) free and weakly bound testosterone concentrations by mathematical modeling.[15] The last approach uses mass action equations to calculate free and weakly bound testosterone concentrations from the concentrations of (1) total testosterone, (2) SHBG, and (3) albumin, and from the association constants for the binding of testosterone to the two binding proteins.

Measurement of Dehydroepiandrosterone and Its Sulfate

Measurements of DHEA or its sulfated conjugate, DHEAS, in serum and plasma are important to investigations of adrenal androgen production, such as the assessment of (1) hyperplasia, (2) adrenal tumors, (3) adrenarche, (4) delayed puberty, and (5) hirsutism.[1] DHEAS in circulation originates primarily from the adrenal glands, although in men some may be derived from the testes. None is produced by the ovaries. DHEA is secreted almost entirely by the adrenal glands.

DHEA concentrations exhibit a circadian rhythm that reflects the secretion of ACTH and also varies during the menstrual cycle. DHEAS concentrations do not exhibit a circadian rhythm because of their longer circulating half-life.

Methodology

Mass spectrometry is the method of choice for measurements of DHEA and DHEAS. Other methods include (1) immunoassays, (2) double-isotope derivative methods, and (3) competitive protein-binding assays. The latter actually measures 5-androstenediol derivatives and uses SHBG as a naturally occurring binding protein. A reference method based on LC-MS/MS has been used for independent evaluation of routine methods. Immunoassays for DHEAS demonstrate significant cross-reactivity with (1) DHEA, (2) androstenedione, and (3) androsterone, yet the relative concentrations of these steroids cause a minimal effect on assay performance.

Reference intervals for serum concentrations of DHEAS and DHEA are listed in Table 50-1 in Chapter 50.

Specimen Collection and Storage

Serum or plasma (preserved with EDTA) is suitable for DHEA or DHEAS immunoassays. Medications such as (1) steroid, (2) ACTH, (3) E_2, or (4) gonadotropin drugs should not be given for 48 hours before sample collection. Early morning collection, before 1030, is preferred for DHEA. Refrigerated samples (4 °C to 8 °C) are stable for up to 14 days; those frozen at −20 °C are stable for about 1 year.

Measurement of 17-Ketosteroids in Urine

The 17-KSs are metabolites of precursors secreted by the (1) adrenal glands, (2) testes, and to some extent the (3) ovaries. In men, approximately one third of the total urinary 17-KSs represent metabolites of testosterone secreted by the testes, whereas most of the remaining two thirds are derived from the steroids produced by the adrenal glands. In women, who normally excrete smaller quantities than men, the total 17-KS concentrations are derived almost exclusively from the adrenal glands.

The bulk of the urinary 17-KSs consists of (1) androsterone, (2) epiandrosterone, (3) etiocholanolone, (4) DHEA, (5) 11-keto- and (6) 11β-hydroxyandrosterone, and (7) 11-keto- and (8) 11β-hydroxyetiocholanolone. DHEA and 11-hydroxy 17-KSs are produced only by the adrenal glands, whereas the others also arise from precursors (androstenedione and testosterone) elaborated by the **gonads.** Thus the main purpose of measuring these steroid metabolites is to assess adrenal androgen production.

Mass spectrometric methods are available for estimating the concentration of total 17-KSs in urine. Ketogenic steroids also have been measured using the Zimmermann reaction, in which an alkaline solution of meta-dinitrobenzene reacts with methylene groups at carbon-16 of the 17-ketosteroids.

Of note, various drugs interfere with the photometric 17-KS assays. Those that produce a positive interference include (1) chlorpromazine, (2) ethinamate, (3) meprobamate, (4) nalidixic acid, (5) penicillin, (6) phenaglycodol, and (7) spironolactone. Drugs that produce a negative interference include (1) chlordiazepoxide, (2) progestational agents, (3) propoxyphene, and (4) reserpine.

Measurement of Anabolic Steroids

Exogenous steroids, such as testosterone and DHT, that are used to improve athletic performance are a challenge for the laboratory to detect and quantify. The ratio of testosterone to epitestosterone has been used for detection of testosterone abuse. A ratio of testosterone to epitestosterone greater than 6:1 suggests exogenous testosterone use and further testing should be performed for confirmation. Others have suggested a ratio of testosterone to LH in the urine as an indication of testosterone doping. Mass spectrometry is commonly used for screening and confirmation.

Measurement of Estrogens in Blood

Both instrumental and immunoassay methods are used to measure estrogens in blood.

Instrumental Methods

Isotope dilution LC-MS/MS methods provide the most accurate and reliable measurement of E_2.[8] The key steps in these method are (1) solvent extraction, (2) chromatographic fractionation, (3) chemical derivatization, and (4) detection. For routine purposes, GC-MS methods have been largely replaced by immunoassays.

Immunoassay

Both indirect (extraction required) and direct (no extraction required) immunoassays are used. The most common antigen used to prepare antibodies for E_2 assays is estradiol-6-(O-carboxymethyl) oxime conjugated to bovine serum albumin. Cross-reactivity with other C_{18} steroids is usually minimal as the 3- and 17-hydroxyl groups are left free. Direct enzyme immunoassays have largely replaced RIAs for routine measurement of E_2 concentrations. Measurement of estrogen concentrations in (1) men, (2) postmenopausal women, and (3) children requires use of more sensitive RIAs. Many of the early immunoassays used organic solvents for selective extraction of E_2 from serum. This is step not only removes E_2 from endogenous binding proteins but also removes other compounds that interfere with the method.

To measure E_2 directly without extraction and chromatography, the steroid must be displaced from its binding proteins. The displacing agents used in commercial methods are often not disclosed, but in some systems effective displacement is achieved by adding 8-anilino-1-naphthalene sulfonic acid (ANS) or a large excess of a competing steroid, such as DHT to the sample.

Specimen Collection and Storage

Serum or plasma (with EDTA or heparin as anticoagulant) are used in the measurement of estrogens. Samples should be centrifuged and separated within 24 hours. Samples may be stored refrigerated for 24 hours or frozen for up to 1 year. E_2 concentrations are increased in liver cirrhosis, and oral contraceptives have been found to alter concentrations. In practice, (1) steroid, (2) ACTH, (3) gonadotropin, or (4) E_2 medications should not be given within 48 hours of sample collection.

Measurement of Progesterone in Blood

Measurement of progesterone in serum or plasma is considered to be the most reliable technique to assess its rate of production.

Methodology

Double isotope derivative methods and competitive protein-binding assays have been applied to the measurement of serum progesterone. These methods require extensive purification of the steroid and are labor intensive. GC procedures using (1) flame ionization, (2) electron capture, or (3) nitrogen detection have been used to improve the accuracy of progesterone analysis. These methods also are time consuming and often require (1) solvent extraction, (2) chromatography, and (3) derivatization before the steroid is quantified. There is a candidate isotope-dilution LC-MS/MS reference method for progesterone determination.[14]

For routine measurement of progesterone, immunoassays using steroid-specific antibodies are preferred. Initial immunoassays for serum progesterone measurement used organic solvents to remove the steroid from endogenous binding proteins, such as **corticosteroid-binding globulin** (transcortin and albumin). Direct (nonextraction) measurement of progesterone in serum or plasma is considered the method of choice for routine applications. A number of different antigens have been used to prepare antisera for progesterone assays. Cross-reactivity is most prominent with 5β-pregnanediol, ranging from 6% to 11%. Both RIA and nonisotopic immunoassays are available for measuring progesterone. Enzyme immunoassays are the methods of choice for measuring progesterone.

Specimen Collection and Storage

Serum or plasma (with heparin or EDTA as anticoagulant) has been used, but should be separated within 24 hours. The patient need not be fasting, and no special handling procedures are necessary. Samples may be stored refrigerated for up to 3 days at 4 °C to 8 °C or for up to 1 year at −20 °C. Patients should not be on any (1) corticosteroid, (2) ACTH, (3) estrogen, or (4) gonadotropin medication for at least 48 hours before specimen collection.

Measurement of Luteinizing Hormone and Follicle-Stimulating Hormone

The α subunit of several pituitary hormones is homologous. These hormones include (1) LH, (2) FSH, (3) growth hormone, (4) chorionic gonadotropin, and (5) thyrotropin. Therefore, analytical methods for measuring LH and FSH must recognize the unique β subunits of these hormones.

Methodology

Two-site (double antibody) heterogeneous immunoassays are currently the methods of choice for measuring gonadotropins, and a wide variety of assays have been adapted to automated platforms. Some commercially available methods attach a capture antibody to the surface of test tubes or plastic beads, whereas others use a paramagnetic label or a microparticle to capture the antibody-antigen complexes. Numerous labels have been used for the second antibody, including (1) radioisotopes, (2) enzymes, (3) fluorophores, and (4) chemiluminescent molecules. In modern immunometric assays, (1) hCG interference has been mostly eliminated (<0.008% cross-reactivity), (2) better assay precision has been achieved (between-assay coefficient of variation [CV] <10%), and (3) detection limits have been lowered (<0.2 IU/L). A low limit of detection for LH assays is especially important in the evaluation of prepubertal children and patients with hypothalamic disorders, because LH concentrations in them are very low.

Calibration of gonadotropin assays is difficult because LH and FSH undergo post-translational modifications that produce a mixture of closely related compounds. The earliest reference material used for calibration of LH and FSH assays was the second international reference preparation (IRP) for human menopausal gonadotropins, isolated from the urine of postmenopausal women. Alterations during metabolism and excretion, however, limited the comparability of this preparation with circulating forms of the hormones, and subsequent calibrators were prepared from extracts derived from the human pituitary gland. Purified pituitary extracts, such as the first and second IRPs for FSH and LH, were available for many years but have been replaced by highly purified extracts that have minimal contamination with cross-reacting glycoproteins. Manufacturers of older immunoassays for LH and FSH used one or more pituitary-derived reference materials for their working calibrators, but recombinant gonadotropin calibrators are now available.

Biases in analytical results still exist between different immunoassay systems (most notably in LH assays), and results have been known to differ by more than 50%, even when calibrated with the same reference preparation.

Specimen Collection and Storage

Serum is the preferred specimen for gonadotropin measurements. Hemolyzed, lipemic, and/or icteric specimens should not be used. Both hormones are stable for 8 days at room temperature, and for 2 weeks at 4 °C; for longer periods, the serum specimen should be frozen at or below −20 °C. Because of (1) episodic, (2) circadian, and (3) cyclic variations in the secretion of gonadotropins, meaningful clinical evaluation of these hormones may require determinations in (1) pooled blood specimens, (2) multiple serial blood specimens, or (3) timed urine specimens. Urine specimens should not contain preservatives; storage at or below −20 °C is recommended.

Comments

Clinically, the pulsatile and episodic release of gonadotropins makes a single blood concentration of FSH or LH difficult to interpret. In adults, concentrations of gonadotropins in blood, particularly LH, may differ as much as threefold between blood specimens collected from the same individual 20 minutes apart. In addition, the lower detection limit of many FSH and LH immunoassays may be within the reference interval for these hormones in healthy adults. In prepubertal children, most blood assays are not capable of measuring normal concentrations because they are so low.

Measurement of Urinary Follicle-Stimulating Hormone and Luteinizing Hormone

To optimize detection limits for gonadotropin assays in children, urinary FSH or LH assays have been used. Some pediatric endocrinologists favor urine assays when investigating pubertal disorders of gonadotropin secretion.

Review Questions

1. In females, follicle-stimulating hormone (FSH) functions to:
   a. induce development of the ovum within the follicle.
   b. maintain bone integrity in premenopausal women.
   c. trigger release of the ovum from the follicle.
   d. induce development of the endometrium.

2. In males, luteinizing hormone (LH) functions to:
   a. induce sperm production by the Leydig cells.
   b. stimulate production of testosterone by Leydig cells.
   c. promote sperm production by the Sertoli cells.
   d. induce synthesis of testosterone by the Sertoli cells.
3. Progesterone is synthesized and secreted by the:
   a. corpus luteum.
   b. placenta.
   c. pituitary gland.
   d. Both A and B are correct.
4. Which of the following hormones is considered to be the most potent of the three biologically active estrogens?
   a. Estriol (E_3)
   b. Estradiol (E_2)
   c. Estrone (E_1)
   d. Progesterone
5. Increased production of progesterone and estrogen from the corpus luteum with gradual lowering of LH and FSH concentrations is characteristic of which phase of the reproductive cycle?
   a. Follicular
   b. Luteal
   c. Ovulatory
   d. Menopausal
6. Which ovarian disorder results in an overall decrease in FSH, LH, estrogen, and progesterone?
   a. Hypogonadotropic hypergonadism
   b. Hypergonadotropic hypogonadism
   c. Hypergonadotropic hypergonadism
   d. Hypogonadotropic hypogonadism
7. In a woman, failure to establish spontaneous periodic menstruation by the age of 16 regardless of whether secondary sex characteristics have developed is referred to as:
   a. primary amenorrhea.
   b. secondary amenorrhea.
   c. precocious puberty.
   d. pseudohermaphroditism.
8. In males, FSH functions to:
   a. enhance muscle mass.
   b. induce production of testosterone.
   c. stimulate spermatogenesis.
   d. induce production of androstenedione.
9. The major estrogen secreted by the ovary is _____, whereas the major product secreted by the placenta is _____.
   a. estriol; estradiol
   b. estradiol; estriol
   c. estrone; estradiol
   d. estriol; estrone
10. The most common form of hypogonadotropic hypogonadism in men results from a deficiency of GnRH in the hypothalamus during embryonic development and is referred to as:
    a. Turner syndrome.
    b. Klinefelter syndrome.
    c. Down syndrome.
    d. Kallmann syndrome.

CHAPTER

44 Pregnancy and Prenatal Testing*

David G. Grenache, Ph.D., M.T. (A.S.C.P.), D.A.B.C.C., F.A.C.B., and Geralyn Lambert-Messerlian, Ph.D., F.A.C.B.

Objectives

1. Define the following:
   - Alpha fetoprotein (AFP)
   - Amnion
   - Amniotic fuid
   - Chorion
   - Conception
   - Embryo
   - Gestation
   - Meconium
   - Nuchal transparency
   - Placenta
   - Human placental lactogen (hPL), or placental lactogen (PL)
   - Prenatal screening
   - Surfactant
2. Outline the events in the normal development of a fetus, beginning with conception and ending with birth.
3. Describe the structure and functions of the following, including hormones synthesized (if any), effect on maternal/fetal health if dysfunctional, and laboratory analyses and results used to determine health or disease:
   - Amnion/amniotic fuid
   - Blastocyst
   - Chorionic villus
   - Corpus luteum
   - Ovaries
   - Placenta
4. List the components of amniotic fuid, and state their specific functions and what laboratory analyses are used to examine amniotic fuid.
5. Describe the major biochemical changes that take place during a normal pregnancy in maternal physiological systems including renal, hemostatic, and endocrine changes.
6. State the clinical significance of the following laboratory analytes in the assessment of maternal and fetal health:
   - Alpha fetoprotein (AFP)
   - Human chorionic gonadotropin (hCG), or chorionic gonadotropin (CG)
   - Inhibin A (inhA)
   - Fetal fibronectin
   - Pregnancy-associated plasma protein A (PAPP-A)
   - Unconjugated estriol (uE_3)
7. Describe the fetal renal, gastrointestinal, hepatic, pulmonary systems, including functions, development and maturation, and how and why these systems are assessed by the laboratory.
8. For the following disorders, list the causes and symptoms, and state the laboratory analytical procedures, specimen requirements, and laboratory results used to assess and diagnose:
   - Anencephaly
   - Down syndrome
   - Eclampsia
   - Ectopic pregnancy
   - HELLP syndrome
   - Hemolytic disease of the newborn (HDN)
   - Hyperemesis gravidarum
   - Preeclampsia
   - Respiratory distress syndrome (RDS)
   - Spina bifida
9. In regard to maternal serum screening for fetal defects, describe the composition, timing during pregnancy and utility of the triple, quad, and integrated tests.
10. Analyze and solve case studies related to disorders of pregnancy and laboratory analysis of these.

Key Words and Definitions

Acute fatty liver of pregnancy A rare, life-threatening complication of pregnancy that occurs in the third trimester or the immediate period after delivery.

Alpha fetoprotein (AFP) A protein produced in the fetal liver that is measured in maternal serum for predicting risk of anencephaly, spina bifida, and Down syndrome in the fetus.

Amniotic fluid Substance derived mostly from fetal urine that protects the developing fetus.

Anencephaly A birth defect characterized by a brain, skull, and scalp that does not develop normally.

Assisted reproductive technologies (ART) Procedures involving the manipulation of eggs or sperm to establish pregnancy in the treatment of infertility.

*The authors gratefully acknowledge the original contributions of E.R. Ashwood and G. J. Knight on which portions of this chapter are based.

Key Words and Definitions—cont'd

Blastocyst A thin-walled hollow structure in early embryonic development that contains a cluster of cells called the inner cell mass from which the embryo arises.

Cholestasis of pregnancy A condition during pregnancy characterized by impaired bile flow allowing bile salts to be deposited in the skin and the placenta.

Chorionic villi One of the minute vascular projections of the fetal chorion that combines with maternal uterine tissue to form the placenta.

CLIA waived tests Tests categorized as "waived" by the FDA under the Clinical Laboratory Improvement Amendments of 1988. These tests employ methodologies that are considered to be so simple and accurate as to render the likelihood of erroneous results negligible.

Conception The union of the sperm and the ovum. Synonymous with fertilization.

Down syndrome A birth defect characterized by having three copies of chromosome 21 rather than the normal two copies. Also known as trisomy 21.

Eclampsia Convulsions and coma occurring in a pregnant woman or a woman who recently gave birth.

Ectopic pregnancy An embryo developing in the fallopian tube or abdomen instead of the uterus.

Embryo A developing infant that has not yet finished organ development (before 10 weeks gestation).

Endometrium The glandular mucous membrane that lines the uterus.

Expected date of confinement (EDC) The date at which an infant is expected to be born, calculated from the date of the last menstrual period (LMP). Also called due date.

Fetal erythroblastosis A severe hemolytic disease of a fetus or newborn infant caused by the production of maternal antibodies against the fetal red blood cells, usually involving rhesus (Rh) blood group incompatibility between the mother and fetus.

Fetal fibronectin (fFN) A protein produced during pregnancy that is thought to function as a "glue" attaching the fetal sac to the uterine lining; a test for fFN in cervicovaginal fluid is used to assess risk of preterm labor.

Fetal lung maturity (FLM) A parameter that determines the likelihood a neonate will develop respiratory distress syndrome.

Fetus A developing infant that has finished organ development (following 10 weeks gestation).

Gestation The process, state or period of carrying an embryo or fetus from conception until birth; by convention, the time is measured clinically from the first day of the last menstrual period (LMP) and reported in weeks; gestational age of the fetus is often estimated by use of ultrasound.

HELLP syndrome A life-threatening pregnancy complication usually considered to be a variant of preeclampsia and usually occurring between the 23rd and 39th weeks. The name is an acronym for the diagnostic features:
H – Hemolysis
EL – Elevated Liver enzymes
LP – Low Platelets.

Hemolytic disease of the newborn (HDN) A disease of the fetus and newborn caused by maternal antibody–mediated fetal erythrocyte destruction.

Human antimouse antibodies (HAMA) Antibodies made by humans that bind mouse proteins. Their presence in body fluids causes both positive and negative interferences in two-site mouse monoclonal antibody-based assays.

Human chorionic gonadotropin (hCG) A placental glycoprotein hormone that stimulates the ovary to produce progesterone.

Human placental lactogen (hPL) A placental hormone, similar in structure and function to growth hormone, that disappears from the blood immediately after delivery.

Hydramnios (or polyhydramnios) An abnormality of pregnancy characterized by an accumulation of excess amniotic fluid.

Hydrops fetalis A condition in which a fetus or newborn baby accumulates fluids, causing swollen arms and legs and impaired breathing.

Hyperemesis gravidarum Extreme, excessive, and persistent vomiting in early pregnancy that may lead to dehydration and malnutrition.

Insulin-like growth factors One of three protein hormones that share structural similarity to insulin.

In vitro fertilization (IVF) A procedure in which (1) eggs (ova) from a woman's ovary are removed, (2) the removed eggs are fertilized with sperm in a laboratory procedure, and (3) the fertilized egg (embryo) is returned to the woman's uterus.

Lamellar bodies Packages of phospholipids that are produced by type II alveolar cells and represent the storage form of surfactant. They are similar in size to platelets and are present in amniotic fluid.

Lamellar body count (LBC) Concentration of lamellar bodies in amniotic fluid. LBC increases as gestation advances. Most electronic cell counters will count the lamellar bodies.

Lanugo A very fine, soft, and usually unpigmented downy hair on the body of a fetus or newborn baby.

Meconium A dark green fecal material that accumulates in the fetal intestines and is discharged at or near the time of birth.

Molar pregnancy A type of pregnancy caused by abnormal proliferation of placental tissue in the uterus. Also known as a hydatidiform mole.

Morula A solid ball of cells resulting from division of a fertilized ovum and from which a blastula is formed.

Multiple of the median (MoM) In clinical screening, the statistic used to normalize analyte values.

Neural tube defect (NTD) A major birth defect resulting from the abnormal development of the neural tube present during embryonic life that gives rise to the central nervous system; the two most common NTDs are spina bifida and anencephaly.

Nuchal translucency (NT) test A measurement of the size of the translucent space behind the neck of the fetus; made using ultrasound between 10 and 14 weeks of pregnancy. NT tends to be increased in chromosome disorders, such as Turner syndrome and Down syndrome.

Key Words and Definitions—cont'd

Oligohydramnios A condition in pregnancy characterized by a deficiency of amniotic fluid.

Omphalocele A birth defect in which the infant's intestine or other abdominal organs protrude from the navel.

Ovulation The release of the ripe egg (ovum) from the ovary.

Parathyroid hormone (PTH) The hormone secreted by the parathyroid glands that controls the concentration of calcium in the blood.

Placenta A membranous vascular organ that develops in female mammals during pregnancy, lining the uterine wall and partially enveloping the fetus, to which it is attached by the umbilical cord. Following birth, the placenta is expelled.

Placental alpha microglobulin-1 (PAMG-1) A protein present in blood and the amniotic fluid and cervico-vaginal discharge of pregnant women.

Polyhydramnios (or hydramnios) The presence of excess amniotic fluid in the uterus.

Preeclampsia A disorder of widespread vascular endothelial malfunction and vasospasm that occurs after 20 weeks gestation and can present as late as 4 to 6 weeks postpartum. It is clinically defined by hypertension and proteinuria, with or without pathologic edema.

Pregnancy The period from conception to birth. It usually lasts 40 weeks, beginning from the first day of the woman's last menstrual period (LMP), and is divided into three trimesters, each lasting 3 months.

Pregnancy-associated plasma protein A (PAPP-A) A protein used in screening tests for Down syndrome.

Premature rupture of membranes (PROM) Breakage of the sac containing the developing fetus and the amniotic fluid prior to the start of labor; rupture before the 37th week of gestation is called preterm PROM (PPROM).

Preterm delivery The birth of an infant before 37 weeks gestation.

Prolactin A pituitary hormone that stimulates and maintains the secretion of milk.

Puerperium The approximate 6-week period lasting from childbirth to the return of normal uterine size.

Pulmonary surfactant A fluid secreted by the cells of the alveoli that serves to reduce the surface tension of pulmonary fluids.

Rapid plasma reagin test (RPR) test Any of a group of serologic tests for syphilis.

Respiratory distress syndrome (RDS) A disease of premature infants caused by a deficiency of lung surfactant.

Smith-Lemli-Opitz syndrome (SLOS) A congenital malformation syndrome caused by deficiency of the enzyme 7-dehydrocholesterol reductase (DHCR7), due to mutation of the DHCR7 gene on chromosome 11.

Spina bifida A congenital disorder caused by the incomplete closure of the embryonic neural tube (see neural tube defect); the most common form is meningomyelocele (also called myelomeningocele).

Triploidy A condition characterized by the individual having three times the haploid number of chromosomes in the cell nucleus.

Trisomy 18 (Edwards syndrome) A genetic disorder caused by the presence of all or part of an extra 18th chromosome (trisomy: three chromosomes).

Trophoblasts The outermost layer of cells of the blastocyst that attaches the fertilized ovum to the uterine wall and serves as a nutritive pathway for the embryo.

Umbilical cord A flexible cordlike structure containing blood vessels and attaching a human or other mammalian fetus to the placenta during gestation.

Vernix caseosa A white cheese-like protective material that covers the skin of a fetus.

Yolk sac A membranous sac attached to an embryo that provides early nourishment in the form of yolk in many animals, including humans where it functions as the circulatory system before internal circulation begins.

Zygote The fertilized ovum or diploid cell resulting from the fusion of two haploid gametes.

The clinical laboratory has an important role in managing **pregnancy.** In contrast to most clinical situations, when treating an expectant mother, a clinician must simultaneously care for both the mother and the child. This chapter reviews (1) the biology of pregnancy, (2) disorders related to pregnancy, and (3) laboratory tests used to detect, evaluate, and monitor both normal and abnormal pregnancies.

Human Pregnancy[9]

To appreciate the role of laboratory tests in pregnancy healthcare, it is necessary to understand fundamental topics, such as (1) **conception**, (2) **embryo** development, (3) fetal growth, (4) the role of the **placenta**, (5) the importance and composition of amniotic fluid, (6) maternal adaptation to pregnancy, and (7) functional maturation of the **fetus**.[9]

Conception, Embryo, and Fetus

In a normal human pregnancy, the time between **gestation** from conception to birth is approximately 40 weeks. This time period is measured from the first day of the last normal menstrual period (LMP or LNMP). The anticipated date of birth of an infant is commonly referred to as the **expected date of confinement (EDC)**. During pregnancy, a woman undergoes dramatic physiological and hormonal changes. In practice, clinicians customarily divide pregnancy into three timed intervals called trimesters, each of which lasts about 13 weeks. By convention, the first trimester, 0 to 13 weeks, begins on the first day of the LMP.

Ovulation occurs on approximately the 14th day of the regular menstrual cycle (see Chapter 43). If conception occurs, the ovum is fertilized, usually in the fallopian tube, and becomes a **zygote**, which is then carried down the tube into

the uterus. The zygote divides, becoming a **morula.** After 50 to 60 cells are present, the morula develops into the primitive **yolk sac**. This becomes a **blastocyst,** which implants into the uterine wall about 5 days after fertilization. The cells on the exterior wall of the blastocyst, **trophoblasts,** synergistically invade the uterine **endometrium** and develop into **chorionic villi**, creating the placenta.

At this stage, the product of conception is referred to as an embryo. A cavity called the amnion forms and enlarges with the accumulation of **amniotic fluid**. Nourished by the placenta and protected by the amniotic fluid, an embryo undergoes rapid cell division, differentiation, and growth. From combinations of (1) ectoderm, (2) mesoderm, and (3) endoderm cell types, organs begin to form through a process called organogenesis. At 10 weeks, an embryo has developed most major structures and is now referred to as a fetus. At 13 weeks, the fetus weighs approximately 13 g and is about 8 cm long.

Rapid fetal growth occurs during the 13 to 26 weeks of the second trimester. By the end of the second trimester, the fetus weighs approximately 700 g and is 30 cm long. Many fetal organs begin to mature. The 26 to 38 weeks of the third trimester is the time interval in which fetal organs complete their prenatal maturation. During this trimester, the growth rate decelerates. At the end of the third trimester, the fetus weighs approximately 3200 g and is about 50 cm long. Term pregnancy is used to define the interval from 37 to 42 weeks. Normal labor, rhythmic uterine contractions, and birth occur during this period.

Placenta

The placenta and the **umbilical cord** form the primary link between fetus and mother. The placenta grows throughout pregnancy and is normally delivered through the birth canal immediately after the birth of the infant.

Function

The placenta (1) keeps the maternal and fetal circulation systems separate, (2) nourishes the fetus, (3) eliminates fetal wastes, and (4) produces hormones vital to pregnancy. It is composed of large collections of fetal vessels called villi, which are surrounded by intervillous spaces in which maternal blood flows. For substances to move from the maternal circulation to the fetal circulation, they must cross through the trophoblast cells and several membranes. The transfer of any substance depends largely on the (1) concentration gradient between the maternal and fetal circulatory systems, (2) presence or absence of circulating binding proteins, (3) lipid solubility of the substance, and (4) presence of facilitated transport, such as ion pumps or receptor-mediated endocytosis (Box 44-1). The placenta is an effective barrier to the movement of large proteins and hydrophobic compounds bound to plasma proteins. Maternal immunoglobulin G (IgG) crosses the placenta via receptor-mediated endocytosis. Because of its long half-life, maternally produced IgG protects a newborn for the first 6 months of life. IgG antibody assays with low limits of detection may be positive in infants up to age 18 months because of maternal antibodies.

BOX 44-1 Normal Placental Transport

No Transport
Most proteins
Thyroid hormones
Maternal IgM, IgA
Maternal and fetal erythrocytes

Limited Passive Transport
Unconjugated steroids
Steroid sulfates
Free fatty acids

Passive Transport
Molecules up to a molecular weight of 5000 Da having lipid solubility
Oxygen
Carbon dioxide
Sodium and chloride
Urea
Ethanol

Active Transport across Cell Membranes
Glucose
Many amino acids
Calcium

Receptor-Mediated Endocytosis
Maternal IgG
Insulin
Low-density lipoprotein

IgA, Immunoglobulin A; IgG, immunoglobulin G; IgM, immunoglobulin M

Placental Hormones

The placenta produces several protein and steroid hormones (Figure 44-1). The major protein hormones are **human chorionic gonadotropin (hCG)** and **human placental lactogen (hPL)**. The steroids include (1) progesterone, (2) estradiol (E_2), (3) estriol (E_3), and (4) estrone (E_1) (see Chapter 43). The placenta secretes most of its products into the maternal circulation with only small amounts reaching the fetal circulation. Generally, hormone production by the placenta increases in proportion to the increase in placental mass. Therefore concentrations of hormones derived from the placenta, such as hPL, increase in maternal peripheral blood as the placenta increases in size. An exception is hCG, which peaks at the end of the first trimester.

Human Chorionic Gonadotropin

One of the most important placental hormones is hCG. It stimulates the ovary to produce progesterone, which, in turn, prevents menstruation, thereby protecting the pregnancy. The chemistry, biochemistry, and methods for hCG are discussed later in this chapter.

Human Placental Lactogen

Human placental lactogen (hPL), also known as placental lactogen (PL), and human chorionic somatomammotropin (hCS), is a single polypeptide chain of 191 amino acids having two intra-molecular disulfide bridges and a molecular mass of 22,279 Da. The structure of PL is exceptionally homologous (96%) with growth hormone (GH) and less so

with **prolactin** (67%). Placental secretion near term is 1 to 2 g/d, the largest of any known human hormone.

PL has many biological activities, including (1) lactogenic, (2) metabolic, (3) somatotropic, (4) luteotropic, (5) erythropoietic, and (6) aldosterone-stimulating effects. Although PL was used in the past to evaluate fetal health, currently no apparent clinical reason exists to measure PL.

Placental Steroids

The placenta produces a wide variety of steroid hormones, including estrogen and progesterone. These steroids are is described in Chapter 43. Maternal cholesterol is the main precursor for placental progesterone production. Biosynthesis of estrogens by the placenta differs from that of the ovaries because the placenta has no 17α-hydroxylase. Thus, each of the estrogens—estrone (E_1), estradiol (E_2), and estriol (E_3)—must be synthesized from C-19 intermediates that already have a hydroxyl group at position 17. In nonpregnant women, the ovaries secrete 100 to 600 μg/d of E_2, of which about 10% is metabolized to E_3. During late pregnancy, the placenta produces 50 to 150 mg/d of E_3 and 15 to 20 mg/d of E_2 and E_1. Secretion of estrogens and progesterone throughout pregnancy ensures (1) appropriate development of the endometrium, (2) uterine growth, (3) adequate uterine blood supply, and (4) preparation of the uterus for labor. Although measurement of E_3 in the third trimester was used in the past to assess fetal health, most obstetricians now consider this practice obsolete. E_3 measurements in the second trimester of pregnancy are useful in predicting fetal trisomy 21 and 18 (see later discussion on prenatal screening for fetal defects).

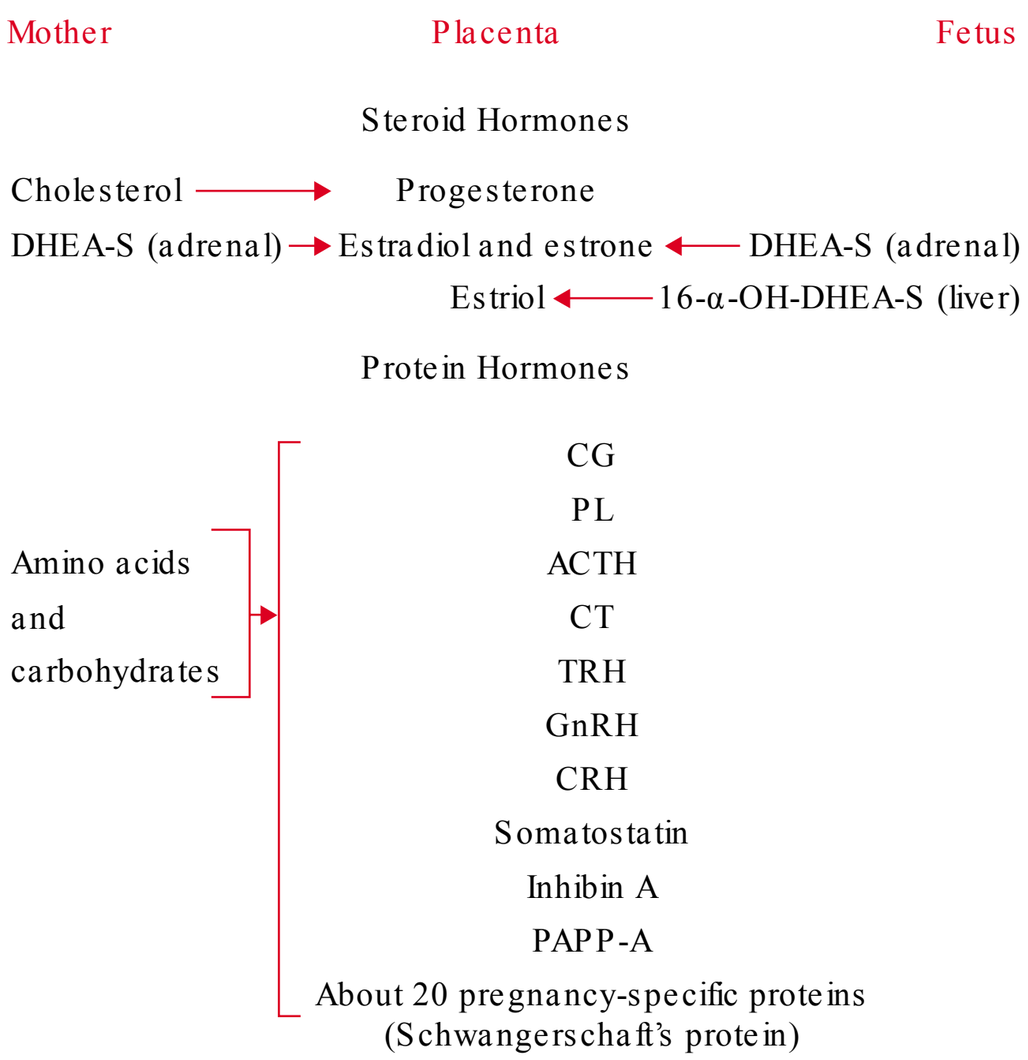

Figure 44-1 Schematic representation of steroid and protein hormone production by the placenta. ACTH, Adrenocorticotropic hormone; CRH, corticotropin-releasing hormone; CT, chorionic thyrotropin; DHEA-S, dehydroepiandrosterone sulfate; GnRH, gonadotropin-releasing hormone; hCG, human chorionic gonadotropin; PAPP-A, pregnancy-associated plasma protein A; PL, placental lactogen; TRH, thyrotropin-releasing hormone.

Amniotic Fluid

Throughout intrauterine life, the fetus lives within an amniotic fluid-filled compartment that (1) provides a medium in which a fetus readily moves, (2) cushions it against possible injury, and (3) helps maintain a constant temperature. Amniotic fluid is a dynamic medium whose volume and chemical composition are controlled within relatively narrow limits.

The volume of amniotic fluid is 200 to 300 mL at 16 weeks, 400 to 1400 mL at 26 weeks, 300 to 2000 mL at 34 weeks, and 300 to 1400 mL at 40 weeks. The volume at any given moment is a function of several interrelated fluid movements, including fetal (1) swallowing of amniotic fluid, (2) urination, (3) intramembranous transport (across the amnion and into the underlying fetal vasculature), and (4) pulmonary excretion of fluid. The fetal tracheobronchial tree is filled with amniotic fluid. Although lung fluid transport contributes a small volume, fetal breathing of this fluid is the mechanism of surfactant transport from the fetal lungs into the amniotic fluid.

Pathological decreases and increases in amniotic fluid volume are encountered frequently. Intrauterine growth retardation and anomalies of the fetal urinary tract, such as bilateral renal agenesis or obstruction of the urethra, are associated with **oligohydramnios**, an abnormally low amniotic fluid volume. Increased fluid volume is known as **hydramnios** (also termed **polyhydramnios**). Conditions associated with hydramnios include (1) maternal diabetes mellitus, (2) severe **hemolytic disease of the newborn (HDN)**, (3) fetal esophageal atresia, (4) multifetal pregnancy, (5) **anencephaly**, and (6) **spina bifida**.

Early in gestation, the composition of the amniotic fluid resembles a complex dialysate of the maternal serum. As a fetus grows, the amniotic fluid changes in several ways (Table 44-1). Most notably, sodium concentration and osmolality decrease and concentrations of (1) urea, (2) creatinine, and (3) uric acid increase. The major lipids of interest are the

TABLE 44-1 Composition of Amniotic Fluid (Mean Values)

	Gestational Age (Week)		
Component	15	25	40
Bicarbonate, mmol/L	16	18	16
Bilirubin, mg/dL	0.13	0.14	0.04
Chloride, mmol/L	111	109	103
Creatinine, mg/dL	0.8	0.9	2.2

phospholipids, whose type and concentrations reflect **fetal lung maturity (FLM)** (discussed further later). Numerous steroid and protein hormones are also present in amniotic fluid and some are useful for diagnosing congenital adrenal hyperplasia (CAH) and fetal thyroid disease.[3]

Early in pregnancy, little if any particulate matter is found in the amniotic fluid. By 16 weeks of gestation, large numbers of cells are present, having been shed from the surfaces of the (1) amnion, (2) skin, and (3) tracheobronchial tree. These cells have proved to be of great utility in antenatal diagnosis. As pregnancy continues to progress, scalp hair and **lanugo** (fine hair on the body of the fetus) are shed into the fluid and contribute to its turbidity. Production of surfactant particles in the lung, termed **lamellar bodies**, greatly increases the haziness of the fluid. At term, amniotic fluid contains gross particles of **vernix caseosa**, the oily substance composed of sebum and desquamated epithelial cells covering the fetal skin.

Normal fetuses do not defecate during pregnancy. If severely stressed, a fetus may pass stool that is called **meconium.** This is heterogeneous material contains many bile pigments and therefore stains the amniotic fluid green. Meconium-stained amniotic fluid is a sign of fetal stress.

Maternal Adaptation

During pregnancy, a woman undergoes dramatic physiologic and hormonal changes. These large quantities of (1) estrogen, (2) progesterone, (3) PL, and (4) corticosteroids produced during pregnancy affect various body systems. In addition, the woman experiences an increase in resistance to angiotensin and a predominance of lipid metabolism over glucose use. As a result of such changes, many of the laboratory reference intervals for nonpregnant patients are not appropriate for pregnant patients. Mean values for selected tests during pregnancy, expressed as a percentage of control means, are presented in Table 44-2.

Hematologic Changes

Maternal blood volume increases during pregnancy by an average of 45%. Plasma volume increases more rapidly than red blood cell mass; therefore, despite augmented erythropoiesis, (1) hemoglobin concentration, (2) erythrocyte count, and (3) hematocrit all decrease during normal pregnancy. Hemoglobin concentrations at term average 12.6 g/dL, compared with 13.3 g/dL for the nonpregnant state. The leukocyte count varies considerably during pregnancy, from 4000 to 13,000/μL. During labor and **puerperium** (the interval immediately after delivery), leukocyte counts may be markedly elevated.

The concentrations of several blood coagulation factors are increased during pregnancy. For example, plasma fibrinogen increases by approximately 65%, from 275 to 450 mg/dL; this increase contributes to the increase in sedimentation rate. Other clotting factors also increase, including factors VII, VIII, IX, and X. Prothrombin and factors V and XII do not change, whereas factors XI and XIII decrease slightly. Even though the platelet count remains unchanged in most women, prothrombin and activated partial thromboplastin times decrease

TABLE 44-2 Mean Serum and Plasma Laboratory Values during Normal Pregnancies Expressed as a Percentage of the Nonpregnant Mean (n = 29)

	Time of Gestation

slightly. Pregnancy increases the risk of thromboembolism to up to five times that of nonpregnant women.

Biochemical

During pregnancy, electrolytes show little change, but concentrations of serum (1) triglycerides, (2) cholesterol, (3) phospholipids, and (4) free fatty acids increase by approximately 40%. The concentration of plasma albumin is decreased to an average of 3.4 g/dL in late pregnancy and plasma globulin concentrations increase slightly. The concentrations of several of the plasma transport proteins, such as sex hormone–binding globulin (SHBG), increase markedly. Serum cholinesterase activity is reduced, whereas alkaline phosphatase activity in serum is tripled, mainly as the result of an increase in very heat-stable alkaline phosphatase of placental origin. In addition, total creatine kinase activity and the isoenzyme CKMB can increase markedly upon delivery.

Renal Function

Pregnancy increases the glomerular filtration rate (GFR) to about 170 mL/min/1.73 m^2 by 20 weeks, and therefore increases the clearance of (1) urea, (2) creatinine, and (3) uric acid. Concentrations of these three analytes are slightly decreased in serum for much of the pregnancy. As term approaches, the GFR begins to return to nonpregnant values. Urea and creatinine concentrations rise slightly during the last 4 weeks. During this time, tubular reabsorption of uric acid increases dramatically, which increases serum uric acid compared with the nonpregnant state. Increased excretion of glucose, up to 1000 mg/d, may occur owing to increased GFR, which presents more fluid to the kidney tubules and therefore lowers the renal glucose threshold. Protein loss in the urine can increase to up to 300 mg/d.

Endocrine

The action of progesterone prevents menses and thus allows pregnancy to continue. In early pregnancy, progesterone is produced by the corpus luteum of the maternal ovary in response to hCG. In later stages, the placenta directly produces enough progesterone to maintain the pregnancy.

Throughout pregnancy, the concentration of **parathyroid hormone (PTH)** is increased by approximately 40% with almost no change in the amount of free calcium, thus suggesting a new set point for the secretion of PTH. During pregnancy, calcitonin does not increase predictably, whereas 1,25-dihydroxyvitamin D is increased and promotes increased intestinal calcium absorption. These changes permit the transfer of large amounts of calcium to the developing fetus.

Elevated estrogen concentration stimulates increased hepatic production of cortisol binding globulin and the hepatic clearance of cortisol decreases. Thus, the absolute plasma concentrations of both total and free cortisol are several times higher during pregnancy. The diurnal rhythm of cortisol, higher in the morning and lower in the evening, is maintained. Plasma concentrations of aldosterone and deoxycorticosterone are increased.

Increasing estrogen concentrations throughout pregnancy increase the secretion of prolactin up to tenfold. Conversely, high estrogen concentrations during pregnancy suppress the secretion of luteinizing hormone (LH) and follicle-stimulating hormone (FSH). Baseline concentrations of other pituitary hormones, such as thyroid-stimulating hormone (TSH), remain approximately unchanged. Although normal pregnancy is a euthyroid state, many changes occur in thyroid function.[3] For example, high concentrations of thyroxine-binding globulin (TBG) increase the concentrations of total thyroxine (T_4) and triiodothyronine (T_3), but free T_4 concentration decreases slightly during the second and third trimesters. Very few (0.2%) pregnant individuals develop hyperthyroidism, and hypothyroidism is also rare (□ 2%). Postpartum thyroid dysfunction is common and is frequently unrecognized. Thyroid screening in pregnancy is recommended for high-risk women but is controversial for others.[3] Thyroid hormone results should be interpreted using trimester-specific and method-specific reference intervals.

Functional Development of the Fetus

Fetal organs mature during the third trimester but not at the same rate. This section reviews the (1) lung, (2) liver, (3) kidneys, and (4) blood maturation in the fetus.

Lungs and Pulmonary Surfactant

In healthy air-breathing lungs, a substance called **pulmonary surfactant** coats the alveolar epithelium and responds to alveolar volume changes by reducing surface tension in the alveolar wall during exhalation. Surfactant is needed because surface tension is an inverse function of the radius of the airway. Thus, small alveoli have a higher collapsing force than larger alveoli. Surfactant opposes the force and keeps the small alveoli from collapsing. Specialized alveolar cells called type II granular pneumocytes synthesize pulmonary surfactant and package it into laminated storage granules called lamellar bodies. These storage granules are 1 to 5 μm in diameter and contain (1) phospholipids, (2) cholesterol, and (3) protein. Production starts as early as 20 weeks of gestation, but adequate amounts do not accumulate until about 36 weeks. Fetal breathing movements transport lamellar bodies into the amniotic fluid. The newborn lung contains 100 times more surfactant per cm^3 than the adult lung. Excessive surfactant is needed at birth as the newborn transitions from breathing amniotic fluid to breathing air. Surfactant overcomes the surface tension produced in water-filled alveoli that are admitting air for the first time.

Pulmonary surfactant is a complex mixture of lipids and proteins; less than 5% is composed of carbohydrates. Most of the lipid is phospholipid, and most of that is lecithin (phosphatidylcholine). Unlike lecithin from other tissues, pulmonary lecithin has two saturated fatty acids, usually palmitoyl groups. Other lipids present are (1) phosphatidylglycerol (PG), (2) phosphatidylinositol (PI), and (3) phosphatidylethanolamine (see Chapter 23). Sphingomyelin is present in very small amounts (2%). The protein fraction of lamellar bodies is approximately 4% and is composed of four surfactant-specific proteins: SP-A, SP-B, SP-C, and SP-D.

Liver

Hematopoiesis (formation and development of blood cells) occurs in the liver during the first two trimesters and is transferred to the fetal bone marrow during the third trimester. The liver is also responsible for (1) production of specific proteins such as albumin and clotting factors, (2) metabolism and detoxification of many compounds, and (3) secretion of substances such as bilirubin. The liver produces **alpha fetoprotein (AFP)**, which is measured as a clinically useful marker (discussed later in this chapter). Detoxification and bilirubin secretion mechanisms are immature until late in pregnancy and even in the first few months after birth. Thus premature infants often have high serum bilirubin concentrations and metabolize drugs poorly.

Kidneys

Toward the end of the first trimester, the fetal kidneys begin to produce urine, which is the main component of amniotic fluid. However, early nephrons cannot produce concentrated urine, and pH regulation is also limited. Complete maturation occurs after birth. Although kidneys are not required for fetal survival, amniotic fluid is required. Without fluid to breathe, the fetal lungs fail to develp properly. Thus newborns without kidneys die of pulmonary failure.

Fetal Blood Development

Fetal blood is produced (1) first by the embryonic yolk sac, (2) then by the liver, and (3) finally by the fetal bone marrow. The yolk sac produces three embryonic hemoglobins: Portland, Gower-1, and Gower-2. These normal embryonic hemoglobins are of little importance in clinical chemistry, because they are present in fetal blood only in the first trimester.

With the switch of erythropoiesis to the fetal liver and spleen, fetal hemoglobin (Hb F) production begins. Hb F consists of two α- and two γ-chains ($\alpha_2\gamma_2$). Small amounts of adult hemoglobin, Hb A ($\alpha_2\beta_2$), are also produced, but Hb F predominates during the remainder of fetal life. As the fetal bone marrow begins red cell production, Hb A production increases. At birth, fetal blood contains 75% Hb F and 25% Hb A. Hb F production rapidly diminishes during the first year of postnatal life. In normal adults, less than 1% of hemoglobin is Hb F. Hb F has a higher affinity for oxygen than does Hb A. Thus, in the placenta, oxygen (1) is released from the maternal Hb A, (2) diffuses into the chorionic villi, and (3) binds to the fetal Hb F. In addition, 2,3-diphosphoglycerate (2,3-DPG) does not bind Hb F and therefore cannot decrease its affinity for oxygen as occurs with Hb A.

Maternal and Fetal Health Assessment

For optimum healthcare during pregnancy, a woman should consult her physician before conception. Preconception evaluation should include (1) a medical, reproductive, and family history; (2) physical examination; and (3) laboratory tests.

Laboratory Testing

The following laboratory tests frequently are recommended as part of a preconception evaluation: (1) hematocrit, (2) blood type and Rh compatibility, (3) erythrocyte antibody screen, (4) Papanicolaou smear (or human papillomavirus [HPV] test), (5) urinalysis, (6) rubella titer, (7) **rapid plasma reagin (RPR) test**, (8) gonococcal and chlamydia DNA test, (9) cystic fibrosis carrier status, (10) human immunodeficiency virus (HIV) antibody, and (11) hepatitis B surface antigen (HBsAg). Depending on demographic risks, genetic testing for disorders such as (1) Tay-Sachs disease, (2) thalassemia, and (3) sickle cell disease may be offered. A careful diet history is warranted. Folic acid supplementation should be recommended to reduce the risk of **neural tube defects**.

Many women consult a physician a few days after a missed menses if they suspect they might be pregnant. A urine hCG test result is positive (meaning that the test detects hCG above an analytical detection limit) in over half of pregnant females on the day of the expected menses, that is, at about 2 weeks after conception. Screening for fetal neural tube defects and **Down syndrome**[10] should be offered to all pregnant patients.[8] Depending on diabetes risk, glucose tolerance testing should be performed immediately or at 24 to 28 weeks (see Chapter 33). Some physicians test selected patients for preterm labor risk at 24 to 30 weeks using a test for **fetal fibronectin (fFN)** in cervicovaginal fluid. Current methods that are used for monitoring fetal well-being include (1) maternal observation and recording of fetal movements, (2) ultrasound examination, and, based on limited evidence, (3) tests that monitor the fetal heart rate during random uterine contractions or fetal movement.

Clinical Specimens

Many different samples are used in clinical laboratory analysis before and during pregnancy. These include (1) paternal saliva, serum, and blood; (2) maternal saliva, serum, blood, and urine; (3) amniotic fluid obtained by amniocentesis or from pools of fluid in the vagina after rupture of the fetal membranes; (4) chorionic villi; (5) fetal blood obtained by percutaneous umbilical blood sampling; and (6) fetal tissue obtained by biopsy.

The technique of amniocentesis is described in Chapter 6. Additional information is found in the section on tests for evaluating FLM later in this chapter. Amniotic fluid is sometimes obtained immediately after transvaginal puncture of the bulging membranes. It is possible to use this fluid for analysis if it is not grossly contaminated with blood or vaginal secretions. Clinicians consider amniocentesis for patients with spontaneously ruptured membranes.

Small samples of placental tissue (chorionic villi) also are used for analysis. They are obtained with a catheter between 9 and 12 weeks gestation. Chorionic villi specimens have been used to (1) identify the fetal chromosomes (the karyotype), (2) determine enzyme activities, or (3) detect specific gene mutations. It is possible to perform this procedure earlier in pregnancy than amniocentesis, but it has a higher rate of fetal loss.

Diagnosis and Dating of Pregnancy

The most important aspects of pregnancy management are detection of pregnancy and establishing accurate estimates of

fetal age. The most useful test for detecting pregnancy is the hCG test.

Qualitative tests for hCG in blood or urine are used primarily to screen for and diagnose pregnancy. Urine hCG tests are usually sufficient to diagnose and confirm a normal pregnancy when it has progressed beyond the first week after the missed period. However, serum hCG tests may detect pregnancy earlier than urine tests, and quantitative hCG tests are able to reveal problems in early pregnancy. In the first 8 weeks of pregnancy, the hCG concentration in maternal serum rises geometrically (Figure 44-2). Detectable amounts (□5 IU/L) are present in the serum 8 to 11 days after conception, which is in the third week of pregnancy as measured from the LMP. In practice, hCG usually becomes detectable in the urine at or around the same time it appears in the serum, although the interval is highly variable. For women aged 13 to 40, serum hCG concentrations of 5 IU/L or greater are consistent with pregnancy. Concentrations in approximately half of pregnant women reach 25 IU/L on the first day of their missed period. The peak concentration occurs at about 8 to 10 weeks and is about 100,000 IU/L. Subsequently, hCG concentrations start to decline and by the end of the second trimester, a 90% reduction from peak concentration has usually occurred. The presence of twins approximately doubles hCG concentrations.

False-positive or increased serum hCG test results have been obtained from qualitative and quantitative assays when **human antimouse antibodies (HAMA)** or other interfering antibodies are present. If suspected, investigative experiments include (1) testing a urine specimen for the presence of hCG, (2) serially diluting the serum to confirm an appropriate dose response, (3) testing the serum using a different hCG method, and (4) retesting the serum after treatment with interfering antibody blocking agents.

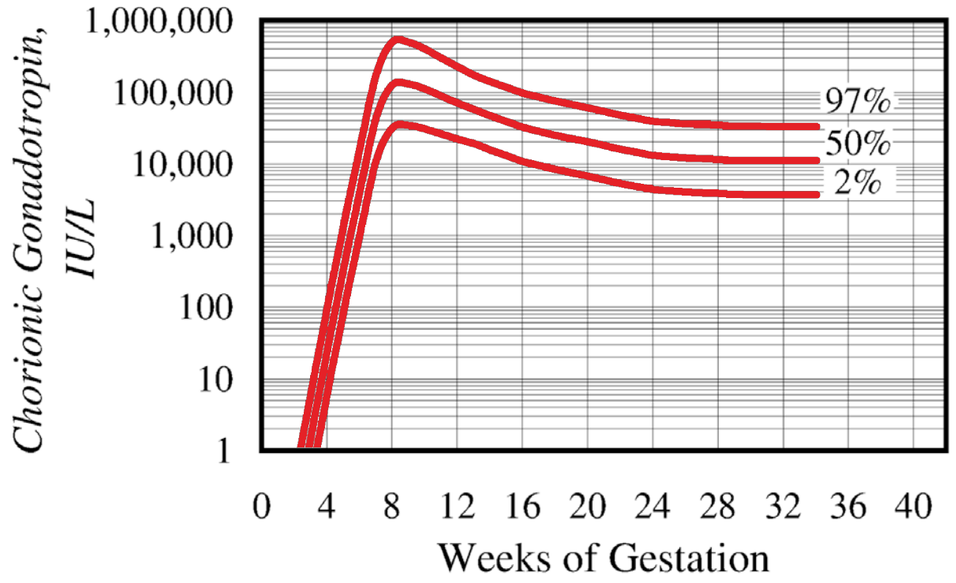

Figure 44-2 Concentration of human chorionic gonadotropin (hCG) in maternal serum as a function of gestational age. Lines represent the 2nd, 50th, and 97th percentiles. The maternal serum values from 14 to 25 weeks are medians calculated from 24,229 pregnancies from testing performed at ARUP Laboratories Inc. from January to October 1997. (Redrawn from Ashwood ER. Evaluating health and maturation of the unborn: the role of the clinical laboratory. Clin Chem 1992;38:1523-1529. Permission granted from Clin Chem.)

Complications of Pregnancy

Although most pregnancies progress without problems, complications can occur in the (1) mother, (2) placenta, or (3) fetus.

Abnormal Pregnancies

Conditions arising primarily in the mother include (1) **ectopic pregnancy**, (2) **hyperemesis gravidarum**, (3) **preeclampsia**, (4) **HELLP syndrome**, (5) liver disease, (6) Graves disease, and (7) HDN. The clinician must distinguish abnormal changes in laboratory tests from normal physiological changes induced by pregnancy (see Table 44-2).

Ectopic Pregnancy and Threatened Abortion[5]

When a fertilized egg implants in a location other than the body of the uterus, the condition is called an ectopic pregnancy. Most abnormal implantations occur in the fallopian tube; they can also occur in the abdomen, although this is rare. Tubal rupture and hemorrhage are serious and life-threatening complications of ectopic pregnancy. About 25% of individuals with an ectopic pregnancy have classic symptoms of (1) lower abdominal pain, (2) vaginal bleeding, and (3) an adnexal mass. Of all individuals with these symptoms, about 15% have an ectopic pregnancy, and a smaller percentage have incomplete or complete spontaneous abortion. A pregnant patient has about a 1 in 200 chance of dying from an ectopic pregnancy. Management of ectopic pregnancy is surgical (by laparoscopy) or medical (with intramuscular administration of methotrexate). Early detection and proper management of ectopic pregnancy are the most effective means of preventing maternal morbidity and mortality.

Preeclampsia and Eclampsia

Preeclampsia is a pregnancy condition characterized by (1) hypertension, (2) proteinuria, and often (3) edema. It occurs late in the second trimester or early in the third trimester, and affecting 5% to 10% of pregnancies. If the mother develops convulsions, the condition is called **eclampsia.** Its cause is not known but research suggests that abnormal formation of the placenta may have a role. Most maternal deaths are due to central nervous system complications, but ischemic liver damage may also occur. The only cure for preeclampsia is delivery of the placenta.

HELLP Syndrome

The HELLP syndrome (hemolysis, elevated liver enzymes, and low platelet counts in association with preeclampsia) is a life-threatening obstetric complication that occurs in 0.1% of pregnancies. Its most prominent features are thrombocytopenia and disseminated intravascular coagulation. Most cases occur between the 27th and 36th weeks of pregnancy, but the syndrome also may occur postpartum. Women typically present with (1) epigastric or right upper quadrant pain, (2) malaise, (3) nausea, (4) vomiting, (5) headache, and (6) jaundice that occurs in 5% of patients. Lactate dehydrogenase (LD) activities may be very high, and alanine aminotransferase

(ALT) and aspartate aminotransferase (AST) activities are usually 2 to 10 times their upper reference limits. Treatment is delivery. Postpartum management of the patient may require plasmapheresis or organ transplantation. Recurrence rates are 3% to 27%.

Liver Disease

Several liver disorders are unique to pregnancy. These include (1) hyperemesis gravidarum, (2) **cholestasis of pregnancy**, and (3) **acute fatty liver of pregnancy**. These disorders must be distinguished from the normal physiological changes of pregnancy (see Table 44-2). Significant changes normally seen in pregnancy include a dilutional decrease in serum albumin and elevation of alkaline phosphatase (from the placenta). Notably, (1) total bilirubin, (2) 5′-nucleotidase, (3) γ-glutamyltranspeptidase (GGT), (4) ALT, and (5) AST are unchanged in mothers with a normal pregnancy. Changes in these analytes may reflect hepatobiliary disease.

Hyperemesis Gravidarum

Hyperemesis gravidarum is characterized by nausea and vomiting and, in severe cases, dehydration and malnutrition. It typically occurs in the first trimester. When hyperemesis is severe enough to cause dehydration, abnormal liver enzyme values—usually less than four times the upper reference limit—are seen in approximately 50% of patients. Mild hyperbilirubinemia may occur. However, significant liver disease does not occur, and liver biopsy results are normal. Low birth weight babies are common, especially for women who develop malnutrition.

Cholestasis of Pregnancy

Cholestasis of pregnancy usually occurs in the third trimester and is manifested clinically by diffuse pruritus and, in 10% of patients, jaundice. Typical features of cholestasis, including pale stools and dark urine, are present and last until delivery. Women who experience cholestasis while taking oral contraceptives usually develop cholestasis of pregnancy. Serum bilirubin rarely exceeds 5 mg/dL. Alkaline phosphatase is typically two to four times the upper reference limit. Aminotransferase enzyme activities are mildly elevated. Prothrombin time may be elevated because of vitamin K malabsorption. Although many clinicians order serum bile acids in this setting, this test is rarely necessary for diagnosis. The condition itself is benign, but is associated with increased risk of premature birth and fetal death. It recurs with subsequent pregnancies.

Acute Fatty Liver of Pregnancy

Acute fatty liver of pregnancy occurs in approximately 1 in 10,000 pregnancies and is characterized by accumulation of microvesicular fat in the hepatocytes. Many cases of this maternal disorder are caused by an inherited mitochondrial fatty acid oxidation disorder in the fetus. The disease typically occurs at week 37 and is manifested clinically by rapid onset of (1) malaise, (2) nausea, (3) vomiting, and (4) abdominal pain. Mild elevations—less than six times the upper reference limits—of the aminotransferases occur, with the AST activity typically greater than that of the ALT. Serum bilirubin is usually greater than 6 mg/dL. Life-threatening hypoglycemia may occur. Hyperuricemia, presumably from tissue destruction and renal failure, is characteristic. Liver histology shows acute fatty infiltration with little necrosis or inflammation. If untreated, fulminant hepatic failure with hepatic encephalopathy results. Treatment is immediate termination of the pregnancy, at which time rapid recovery usually occurs. Infant and maternal mortality is approximately 50% and 20%.

Non–Pregnancy-Related Liver Disease in Pregnancy

Pregnancy does not preclude the acquisition or aggravation of non–pregnancy-related liver disease. Thus, cholestasis during pregnancy may reflect the presence of (1) hepatotoxicity from drugs, (2) primary biliary cirrhosis, (3) Dubin-Johnson syndrome, or (4) cholelithiasis (see Chapter 37).

Viral hepatitis occurs with the same frequency in pregnancy as would be expected in a comparable age group. Women who acquire hepatitis B late in pregnancy or who are chronic carriers are likely to transmit the disease to their babies. This is especially so if the mother is hepatitis B e antigen (HBeAg) positive. The outcome in the infant varies from fulminant hepatitis (rare and usually in anti–HBeAg-positive mothers) to mild hepatitis to chronic hepatitis (the usual outcome in 90% of chronically infected woman). In the US, pregnant women are screened for hepatitis B with HBsAg testing. If positive, their babies are immunized with hepatitis B immune globulin and hepatitis B vaccine. Babies born to hepatitis C–positive mothers usually have the passively transmitted antibody for several months, but transmission of active hepatitis is unusual. Because there is no known treatment for the newborn, screening is not recommended for hepatitis C virus infection.

Neonatal Thyroid Function

During the first trimester of pregnancy, the fetus is dependent on the mother for its supply of thyroid hormone. Low maternal thyroid hormone concentrations (overt or subclinical hypothyroidism) have been associated with adverse outcomes, such as (1) **preterm delivery**, (2) fetal death, and (3) a reduced intelligence quotient (IQ) in children. Later in pregnancy, the fetal thyroid-pituitary axis functions independently from the mother's axis in most cases. However, if the mother has preexisting Graves disease (see Chapter 42), her autoantibodies are able to cross the placenta and stimulate the fetal thyroid gland. Thus, it is possible for the fetus to develop hyperthyroidism.

Hemolytic Disease of the Newborn

HDN is a fetal hemolytic disorder caused by maternal antibodies directed against antigen on fetal erythrocytes. Commonly used synonyms for this disorder are (1) isoimmunization disease, (2) Rh isoimmune disease, (3) Rh disease, (4) D isoimmunization, and (5) **fetal erythroblastosis**. Any of a large number of erythrocyte surface antigens, such as (1) Rh(CcDEe), (2) A, (3) B, (4) Kell, (5) Duffy, (6) Kidd, and (7) others, may be responsible for isoimmune hemolysis. In the past, disease severity was assessed by measuring the amount of bilirubin in the amniotic fluid. Presently ultrasonographic

determination of middle fetal cerebral artery velocity is replacing amniotic fluid bilirubin for the assessment of fetal hemolytic anemia.

Causative Factors and Consequences

Maternal sensitization may occur in response to blood transfusion or a pregnancy in which the fetus has a blood cell antigen that the mother lacks. Antibodies against RhD are the most common cause of HDN, although antibodies against other erythrocyte antigens also cause disease. The resulting antibodies are actively transported across the placenta and into the fetus, where they cause destruction of fetal erythrocytes. The severity of the resulting hemolysis is influenced by antibody (1) specificity, (2) titer, and (3) transfer rate, as well as by the (4) functional maturity of the fetal spleen in which sensitized erythrocytes are destroyed.

With HDN, fetal erythrocytes are destroyed. The resulting anemia stimulates the fetal marrow and extramedullary erythropoiesis in the liver and spleen to replace destroyed erythrocytes. Extramedullary erythropoiesis destroys hepatocytes and leads to decreased production of serum albumin and decreased oncotic pressure in the intravascular space. When severe, these changes lead to congestive heart failure and generalized fetal edema, a condition referred to as **hydrops fetalis**, which carries a very grave prognosis. Without therapeutic intervention, intrauterine demise soon follows.

Clinical Management of Sensitized Mothers

To identify sensitized women, an alloantibody screen is performed at the first prenatal visit. If an antibody to an erythrocyte antigen is identified, the titer is determined. The critical anti-RhD titer, defined as the titer associated with risk for fetal hydrops, is usually 1:8 to 1:32, although studies of critical titer are quite disparate. For all sensitized women, the paternal erythrocyte phenotype is determined. If the father is RhD negative, then no follow-up studies are required. If he is D positive, then zygosity (presence of one or two copies of the gene) is determined. Although this has historically been estimated from Rh antigen phenotypes, DNA testing for RhD zygosity is more reliable. If the father is homozygous, all of his offspring are assumed to be RhD positive, negating the need for fetal RhD testing. Fetal RhD genotyping from cultured amniocytes is required if the father is heterozygous or is not available for testing. To guard against a false negative caused by a paternal RhD gene rearrangement (occurring in about 1.5% of Caucasians), the father is also genotyped. A frequent occurrence in those of African ancestry is an RhD pseudogene; the patient is RhD negative by serology, but RhD positive on genotype. If the fetus is RhD genotype positive, the mother (who is RhD negative serologically) should be tested for RhD genotype. In practice, laboratories have begun to offer fetal Rh genotyping using cell-free fetal DNA that circulates in maternal blood.

For sensitized mothers with an at-risk fetus, serial titers are performed on maternal serum every month until 24 weeks gestation, then every 2 weeks thereafter. If a critical titer anti-D is detected, ultrasound Doppler measurements are used to determine the peak velocity of blood flow in the fetal middle cerebral artery. Higher velocity is a strong indicator of fetal anemia. If Doppler velocimetry is not available, amniocentesis is performed every 10 to 14 days to assess the bilirubin concentration in amniotic fluid. The procedure to estimate the bilirubin concentration was originally called ΔOD_{450} (change in optical density at a wavelength of 450 nm), and that term is still encountered, but now the preferred clinical chemistry term is ΔA_{450} (change in absorbance at a wavelength of 450 nm). Serial testing is indicated every 10 to 14 days. Decreasing values are reassuring and indicate an unaffected or RhD-negative fetus. Values that plateau or increase suggest active hemolysis, which may require therapeutic intervention including ultrasound-guided umbilical blood sampling to determine (1) fetal blood type, (2) hemoglobin concentration, (3) presence of an antibody, (4) reticulocyte count, and (5) total bilirubin concentration. Intrauterine intravascular blood transfusion is performed if indicated. If fetal pulmonary maturation has occurred (usually 35 weeks or greater), delivery is indicated.

Trophoblastic Disease

Serum hCG determinations are very useful for monitoring patients with (1) trophoblastic disease, (2) germ cell–derived neoplasms or, rarely, (3) other hCG- producing tumors. Use of hCG in these diseases is discussed in Chapter 20.

Fetal Anomalies

Fetal anomalies that are detected by prenatal screening include (1) **neural tube defects**, (2) Down syndrome, and (3) **trisomy 18**.

Neural Tube Defects

Neural tube defects are serious abnormalities that occur early in embryonic development. By 19 days after fertilization, the area that is to form the central nervous system (brain and spinal cord) has differentiated into a plate of cells. The flat plate then rolls up, and its edges fuse into a hollow neural tube that drops into the embryo to develop just underneath what will become the skin of the back. Neural tube formation is normally complete 4 weeks after fertilization. Failure of neural tube fusion leads to permanent developmental defects of the brain, spinal cord, or both. These defects are called (1) anencephaly, (2) spina bifida (the most common defect being a meningomyelocele), and (3) encephalocele. Although many causes are known, about 90% fall into the classification of multifactorial inheritance. Folic acid deficiency is clearly associated with increased frequency of neural tube closure defects. Since 1997, grain products in the United States and Canada have been fortified with 140 μg folic acid/100 g, but the amount added is unlikely to be sufficient to reduce birth prevalence by more than about 30%. Most vitamin supplements contain 400 μg of folic acid, which is the dose recommended daily by authorities.

The birth prevalence of open neural tube defects varies with factors such as (1) geographic location (higher in the Eastern United States, lower in the West), (2) race (lower in black), (3) ethnicity (higher in Scotch-Irish), (4) family history (higher with prior births of affected individuals), and (5) maternal weight (higher in obese women). An average

figure for the United States is 1 open neural tube defect per 1000 pregnancies (about 1 in 2000 for each individual defect).

Down Syndrome

Down syndrome (trisomy 21) is the most common serious disorder of the autosomal chromosomes, occurring in 1 in 700 live births. An extra copy of chromosome 21 produces a phenotype consisting of (1) moderate to severe mental retardation, (2) hypotonia (low muscle tone), (3) congenital heart defects, and (4) a flat facial profile. Most often an affected child has three copies of chromosome 21, but 5% of cases are caused by translocations (a transfer of a chromosomal segment to a new position) and 1% of cases are mosaics (the presence of two or more populations of cells with different genotypes in one individual who has developed from a single fertilized egg). A woman's risk of having a Down syndrome baby increases slowly up to age 30 and then steadily increases between ages 30 and 45 to a plateau.

Trisomy 18

Trisomy 18 (Edwards syndrome) is caused by a nondisjunction event (failure either of two homologous chromosomes to pass to separate cells during the first meiotic division or of the two chromatids of a chromosome to pass to separate cells during mitosis or during the second meiotic division) during meiosis. T is results in a fetus having an extra copy of chromosome 18. Although it occurs in only 1 in 8,000 births, it is probably the most common chromosome defect at the time of conception. T e dramatic change in prevalence is due to the very high fetal loss rate both before 8 weeks (>80%) and during the second and third trimesters (□70%). Approximately 25% of affected fetuses have meningomyelocele (spina bifida) or **omphalocele** (abdominal wall defect). A high cesarean section rate has been reported for undiagnosed cases. Following birth, 50% of infants die within the first 5 days and 90% die within 100 days.

Preterm Delivery

T e leading cause of neonatal morbidity and mortality in the United States is preterm delivery, defined as delivery before 37 weeks gestation. Approximately 300,000 to 500,000 preterm births occur each year.[11] Rupture of the fetal membranes before the onset of uterine contractions is known as **premature rupture of membranes (PROM)**. When this occurs at less than 37 completed weeks gestation, it is referred to as preterm PROM and is responsible for nearly one third of preterm deliveries.

T e cause of preterm labor is unknown, but it is likely that many factors are involved. Several mechanisms have been supported by a considerable amount of clinical and experimental evidence and include (1) pathological distention of the uterus, (2) decidual hemorrhage, (3) activation of the maternal-fetal hypothalamic-pituitary-adrenal axis, and (4) intrauterine infection or inflammation. fFN may be used for evaluating patients suspected of having preterm labor. T e fFN test is described later, in the section entitled "Analytical Methodology."

Premature Rupture of Membranes

PROM is a complication in 3% of pregnancies. Risk factors for preterm PROM include (1) a history of preterm PROM, (2) genital tract infection, (3) antepartum bleeding, and (4) smoking. Most women who experience PROM will deliver their infants within 1 week. Management of preterm PROM varies according to the gestational age of the fetus and the presence or absence of maternal/fetal infection. For PROM that occurs at 34 to 36 weeks gestation, delivery of the infant has been shown to reduce maternal and fetal infection rates compared with expectant management. When it occurs at 32 to 33 weeks, FLM might assist in decision-making regarding delivery. If the fetal lungs are immature, conservative management with close fetal monitoring is necessary in conjunction with antibiotic therapy and administration of corticosteroids to accelerate lung development. Because of the high risk of severe neonatal morbidity and mortality, women with PROM at less than 32 weeks of gestation are managed conservatively in an attempt to prolong pregnancy to 32 weeks. Interventions include (1) antibiotic therapy, (2) administration of medications to suppress preterm labor (tocolytics), and (3) fetal monitoring.

Fetal Lung Maturity

Respiratory distress syndrome (RDS) is the most common critical problem encountered in clinical management of preterm newborns. T e risk of RDS is inversely related to gestational age at the time of birth. Affected infants require supplemental oxygen and mechanical ventilation to remain properly oxygenated. T e disorder is caused by a deficiency of pulmonary sur*f*actant. In healthy lungs, surfactant coats the alveolar epithelium and responds to alveolar volume changes by reducing surface tension in the alveolar wall during expiration. When the quantity of surfactant is deficient, many of the alveoli collapse on expiration and thereby overinflate the remaining airways. T e lungs become progressively noncompliant (rigid), and blood flowing through the capillary beds of collapsed alveoli fails to oxygenate. During the first few hours of life, affected infants develop (1) tachypnea with or without cyanosis, (2) nasal flaring, (3) expiratory grunting, and (4) intercostal retractions. T e disease worsens during the next few days and usually is worse on the third or fourth day of life. Infants at risk for developing RDS have been treated with intratracheal administration of exogenous surfactant immediately at birth.

Prenatal Screening for Fetal Defects

Prenatal screening is the process of identifying pregnancies at suf ciently high risk of a serious birth defect, such as Down syndrome, to warrant invasive diagnostic testing.[1,12] Before 2003, most obstetricians offered amniocentesis for fetal karyotype determination to all mothers who would be 35 years of age or older at the time of birth. However, in 2002, almost 14% of pregnant women in the United States were 35 or older, and these women accounted for 51% of Down syndrome pregnancies. T erefore, if maternal age alone were used for

screening, half of Down syndrome pregnancies would not be detected, and cases in younger women would not be detected at all. The risk for Down syndrome calculated using screening is more accurate than the use of maternal age alone, and it is now recommended by the American College of Obstetricians and Gynecologists (ACOG) to offer screening to women of all ages.

Terminology and Method of Risk Calculation in Prenatal Screening

Calculation of risk in prenatal screening depends on the pregnancy's prior risk and the pattern of test results.

Multiple of the Median

In clinical screening, the **multiple of the median (MoM)** is the statistic used to normalize analyte values. The initial step in calculating a MoM is to develop a set of median values for each week (or, preferably, each day) of gestation, using the laboratory's own assay values measured on the population to be screened. Individual test results are then expressed as the MoM by dividing each individual analyte value by the median at the relevant gestational age. The MoM is now universally used as a common factor for converting analyte values into an interpretative unit and serves as the starting point for calculating screening results for (1) neural tube defects, (2) Down syndrome, and (3) trisomy 18.

Calculating Individualized Patient-Specific Risks Using Multiple Biochemical Measurements

Measurements of each analyte are made on a maternal serum sample, and the results in mass units are converted to MoM for the appropriate week (or day) of gestation. This MoM value is then adjusted for other variables, such as maternal weight and race (as described later in this chapter). The individualized risk (patient-specific risk) for any given condition is determined by multiplying the a priori (or pre-test) risk for that condition by a likelihood ratio that is calculated using the woman's MoM values as shown in the following equation:

$$\text{Patient risk} = \textit{A priori risk} \times \text{Likelihood ratio}$$

The a priori risk is obtained from large epidemiologic studies that ascertain the prevalence for the condition under consideration. For example, a woman's age is used to define her a priori risk for having a fetus with Down syndrome. The likelihood ratio is determined by calculating the ratio of the heights of the affected and unaffected overlapping population distributions for any specified MoM value. When multiple tests are used, a single likelihood ratio is calculated using the overlapping distributions for each test but with the correlation between tests taken into account. This final risk is the screening variable upon which clinical decisions are made.

Second Trimester Screening Tests

Maternal serum screening began in the 1970s with the use of second trimester serum testing for neural tube defects and progressed to include screening for Down syndrome and trisomy 18.

Neural Tube Defects

In the early 1970s, Brock and colleagues demonstrated that AFP concentrations were increased in the amniotic fluid of mothers carrying fetuses affected with an open neural tube defect. Subsequently, it was shown that AFP concentrations also were increased in the maternal serum of affected pregnancies. However, the distribution of AFP concentrations in serum in affected and unaffected pregnancies overlapped considerably indicating that maternal serum AFP would be useful only as an initial screening test to identify women at high risk for having an affected fetus. These women would then need to be referred for diagnostic procedures, such as (1) high-resolution ultrasound, (2) measurement of AFP, and (3) measurement of acetylcholinesterase in amniotic fluid to determine whether the fetus had an open neural tube defect. The use of maternal serum AFP to screen for open neural tube defects is a standard of care in the United States.

Down Syndrome

In 1984, an association between second trimester maternal serum AFP concentrations and fetal Down syndrome was reported.[4] Maternal serum AFP concentrations are about 25% lower in Down syndrome than in unaffected pregnancies. This finding resulted in the use of AFP measurements in screening programs for Down syndrome. Subsequently, (1) unconjugated estriol (uE_3), (2) hCG, and (3) inhibin A (inhA) were added to screening regiments. This resulted in the use of "quadruple test" being commonly offered and found to provide a detection rate of approximately 80% for Down syndrome.

Trisomy 18

Prenatal screening studies have found that fetal trisomy 18 has a distinctive triple marker pattern that is different from the Down syndrome pattern (Table 44-3). For example, a risk-based algorithm has demonstrated that at a second trimester risk cutoff of 1:100, 60% of trisomy 18 pregnancies could be identified with about 0.5% of women having an initial positive screen.

Other Aneuploidies

Although chromosome disorders other than trisomies 21 and 18 are not part of routine screening, the marker patterns exhibited in maternal serum for some aneuploidies are similar. For example, hydropic Turner syndrome and **triploidy** of paternal origin have serum marker patterns resembling that of a Down syndrome pregnancy and sometimes are identified as high risk using this algorithm. Similarly, Turner syndrome without hydrops and triploidy of maternal origin are sometimes identified by the trisomy 18 risk algorithm. The pattern for trisomy 13 is variable (see Table 44-3).

Newer Screening Algorithms

Following extensive use of screening tests in the second trimester, newer tests have been introduced that use maternal serum collected in the first trimester.

First Trimester Combined Test

For patients seeking early diagnosis, screening for Down syndrome in the first trimester (10 to 13 weeks gestation) is

TABLE 44-3 Conditions Associated with Various Maternal Serum Screening Result Patterns

	Second Trimester				First Trimester		
Condition	AFP	hCG	uE_3	inhA	PAPP-A	hCG	NT
Amniocentesis	Normal to high	—	—	—	—	—	—
Anencephaly	Very high	—	Very low	—	—	—	—
Congenital nephrosis, duodenal atresia, encephalocele, esophageal atresia, gastroschisis, hydrocephalus, Meckel syndrome, omphalocele, sacrococcygeal teratoma	High	—	—	—	—	—	—
Cystic hygroma	High	—	—	—	—	—	Increased
Down syndrome	Low	High	Low	High	Low	High	Increased
Fetal blood contamination	High to very high	Unchanged	Unchanged	Unchanged	—	—	—
Molar pregnancy	Very low	Very high	Very low	Normal	—	—	—
Molar pregnancy (partial)	Low to normal	Very high	Low to normal	Normal	—	—	—

AFP, Alpha fetoprotein; hCG, human chorionic gonadotropin; inhA, inhibin A; NT, nuchal translucency; PAPP-A, pregnancy-associated plasma protein A; uE_3, unconjugated estriol.

available.[13] This is screening involves measurement of (1) maternal serum **pregnancy-associated plasma protein-A (PAPP-A)**, (2) hCG, and (3) fetal **nuchal translucency (NT) test**, the subcutaneous space between the skin and the cervical spine.

In 2003 and 2005,[4] two independent multicenter trials demonstrated that a combination of NT and the measurements of PAPP-A and hCG (termed the combined test) was comparable or slightly better than the second trimester quadruple test for Down syndrome screening, detecting about 85% of cases at a 5% false-positive rate. Also, a large study with comprehensive outcome tracking suggests that the detection rate for trisomy 18 is about 80% at a 0.3% positive rate.[4]

Integrated Test

The integrated test takes advantage of first and second trimester markers and avoids most of the limitations of stand-alone first trimester screening (Figure 44-3). With this approach, measurements of NT and PAPP-A are made in the first trimester but are usually not interpreted or acted upon until testing in the second trimester is complete. In the second trimester, a second blood sample is collected and a quadruple test performed. Results from all six tests (1) NT, (2) PAPP-A, (3) AFP, (4) uE_3, (5) hCG, and (6) inhA are then combined into a single risk estimate. This approach detects 85% of Down syndrome cases at only a 1% false-positive rate.

Follow-Up Testing for Women with Screen-Positive Results

Recommended follow-up testing depends on the types of positive results obtained.

Neural Tube Defects[14]

Women who have a positive screening test result for an open neural tube defect should be offered genetic counseling and further testing. A low-resolution ultrasound examination may verify gestational age and identify other possible reasons for the increased AFP test results such as (1) inaccurate gestational dating, (2) recent fetal demise, (3) twins. Patients who have an unexplained

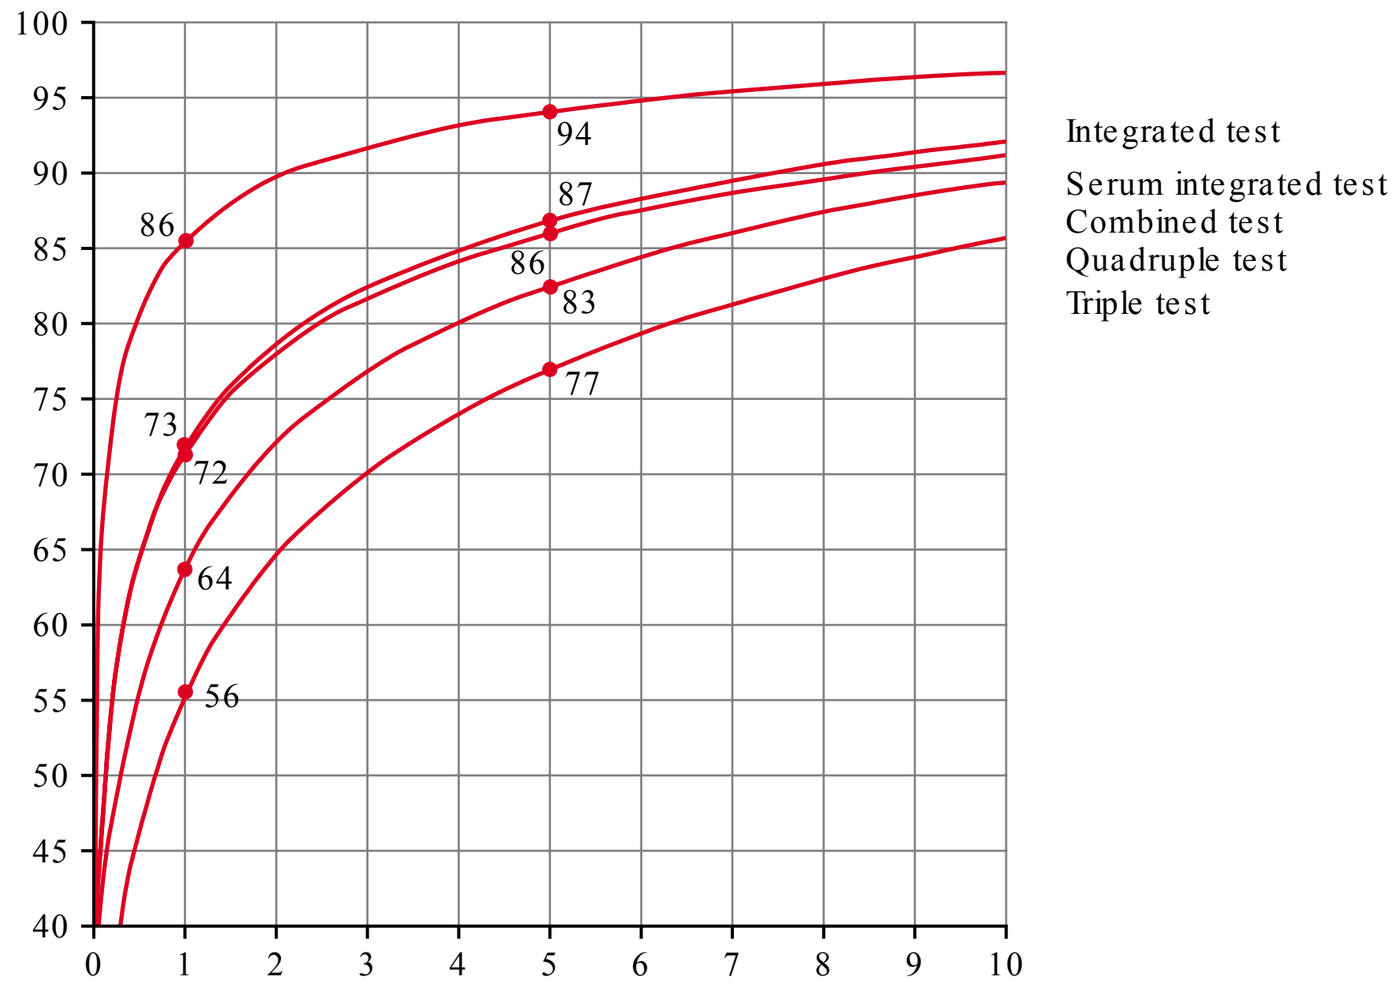

Figure 44-3 Relative performance of different prenatal screening tests.

high maternal serum AFP result are offered high-resolution ultrasound and/or amniocentesis for measurement of amniotic fluid AFP. Compared with maternal serum, the distribution of amniotic fluid AFP concentrations in pregnancies affected by open neural tube defects is far more separated from unaffected pregnancies. However, amniotic fluid AFP measurements are not by themselves diagnostic because of rare false-positive results. If the amniotic fluid is contaminated with even a small amount of fetal blood, as many as 2% to 3% of results can be falsely positive. Down syndrome. Women who have a positive screening test result for Down syndrome are usually referred for genetic counseling and further testing. A low-resolution ultrasound examination may be offered as a way to verify gestational age and to identify other possible reasons for the positive test result. One of the most common reasons for increased Down syndrome risk in the second trimester is overestimated gestational age.

Trisomy 18

In contrast to screening protocols for open neural tube defects and Down syndrome, a dating ultrasound is not recommended as the first step after a finding of increased risk of trisomy 18. The second trimester serum marker pattern (Figure 44-4) is not consistent with incorrect gestational dating, and amniocentesis should be offered. A high proportion of fetuses with trisomy 18 will have abnormal but non-diagnostic second trimester ultrasound findings (e.g., heart defects and clenched fists). Chorionic villi sampling (CVS) may be offered to patients at high risk of trisomy 18 based on first trimester screening results.

Adjustments for Factors That Influence Screening Measurements

Prenatal screening for both open neural tube defects and Down syndrome is optimized when each woman's analyte values are compared with those of other women (the reference group). In addition to gestational age, this "similarity" extends to other factors that have been shown to affect analyte concentrations, including (1) maternal weight, (2) race, (3) insulin-dependent diabetes (IDD), (4) multiple pregnancy, and (5) use of assisted reproduction. Taking into account these factors enhances the accuracy of the interpretation.

Maternal Weight

As maternal weight increases, the average concentration of analyte values decreases, because a fixed amount of analyte is diluted in an increased maternal blood volume. Maternal weight is taken into account for all serum markers by adjusting each woman's MoM values by a factor corresponding to the expected MoM value for women with her weight. Distributions of maternal weight vary within each racial group with Asian women tending to have lower maternal weights than Caucasians and with blacks weighing more. It is optimal to apply adjustment equations for each racial group to correct marker concentrations for weight.

Maternal Race

For second trimester markers, black women have maternal serum AFP and hCG concentrations that are 10% to 15% higher than those found in Caucasian women. InhA concentrations are about 8% lower in blacks, and uE_3 concentrations are not different in these two populations.

Insulin-Dependent Diabetes

Maternal serum AFP values in women who require insulin before pregnancy have been reported to be systematically

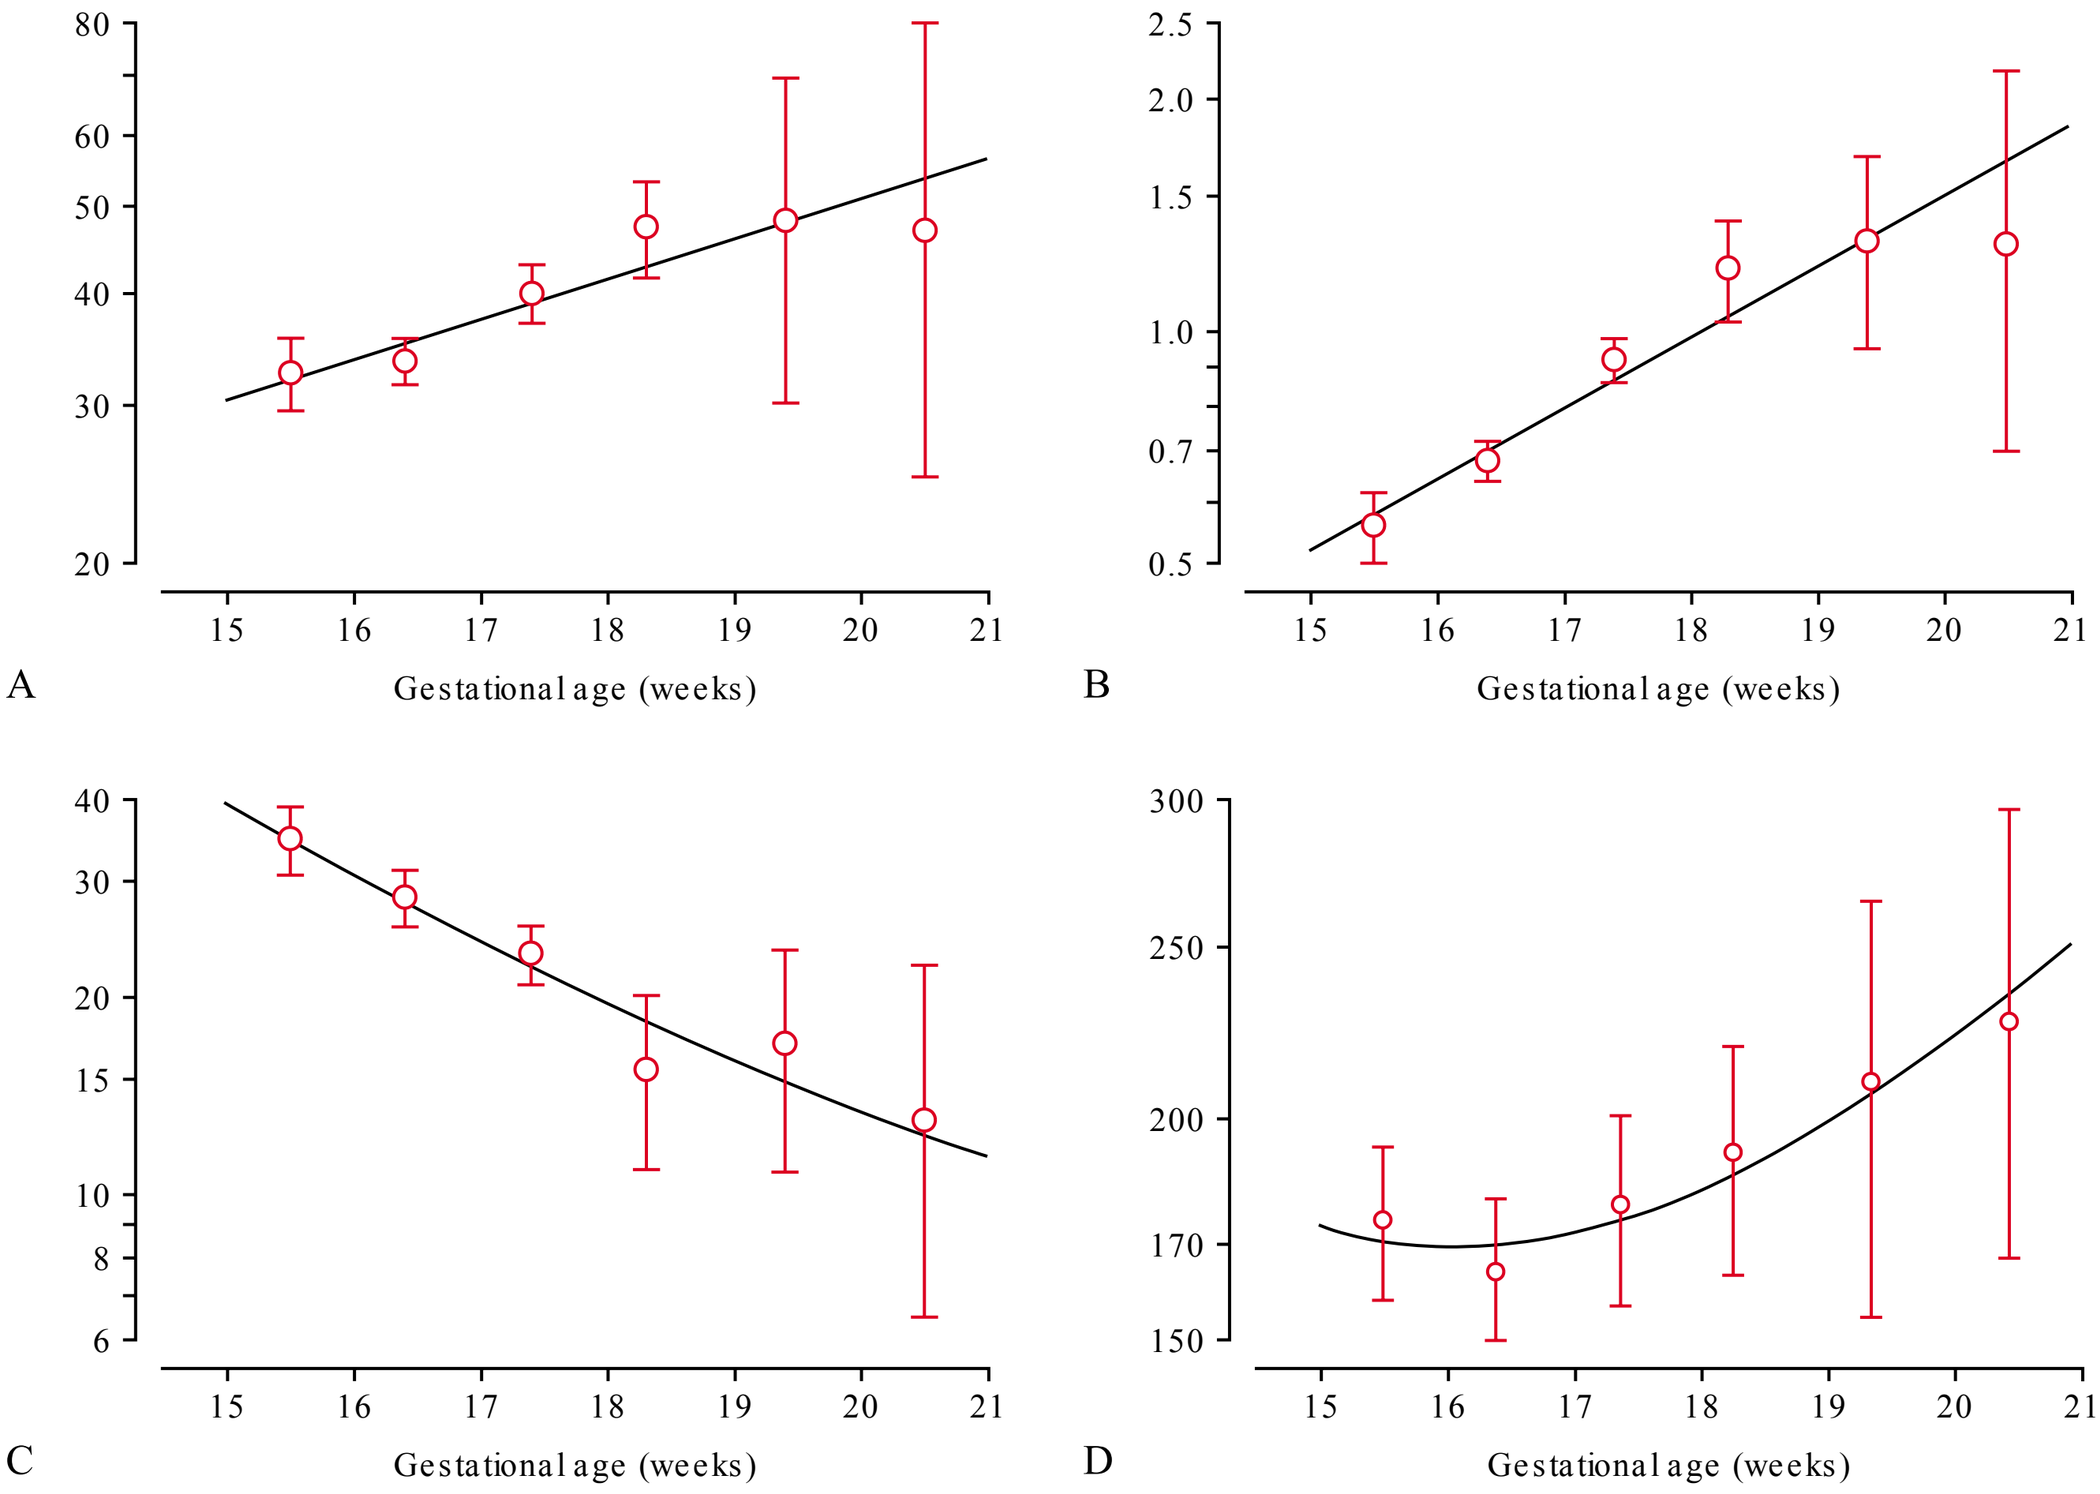

Figure 44-4 Typical median values for maternal serum alpha fetoprotein (AFP), unconjugated estriol (uE_3), human chorionic gonadotropin (hCG), and inhibin A (inhA) in the second trimester. The observed average gestational age is plotted on the horizontal axis, and the median of that week's marker measurements is plotted on the vertical logarithmic axis.

lower by about 20% (0.88 MoM). Women with type 2 diabetes, taking insulin or oral hypoglycemic agents, or on dietary restriction before pregnancy, also show reduced second trimester maternal serum AFP concentrations.

Twin Pregnancy

Maternal serum analyte concentrations in twin pregnancies are about twice the concentration found in singleton pregnancies. For example, the median and MoM values for the analytes measured in unaffected twin pregnancy are (1) AFP [2.0], (2) uE_3 [1.7], (3) hCG [1.9], (4) inhA [2.0] , and (5) PAPP-A [1.8].

Calculation of an approximate risk (sometimes called a pseudorisk) for twin pregnancy is possible. T is is accomplished by dividing the MoM value for each analyte by the corresponding median found in unaffected twin pregnancies.

Pregnancies Achieved by Assisted Reproductive Technologies

As women are choosing to conceive at older ages, the use of **assisted reproductive technologies (ART)**, such as **in vitro fertilization (IVF)**, is increasing. Women who achieve pregnancy by IVF are about twice as likely to have a positive result of second-trimester Down syndrome screening than are women who achieve pregnancy spontaneously. T e increased rate is avoided with adjustment of MoM values for uE_3 (reduced to 0.9 MoM), hCG (increased to 1.0), and inhA (increased 1.2). T ese corrections restore an appropriate screen-positive rate. Pregnancies achieved by intrauterine insemination, with or without ovulation induction, show a similar trend in marker concentrations.

Analytical Methodology

In this section, methodologies for the measurement of (1) hCG, (2) AFP, (3) uE_3, (4) inhA, (5) PAPP-A, (6) fFN, (7) amniotic fluid bilirubin, and (8) tests for FLM are reviewed.

Human Chorionic Gonadotropin

Human chorionic gonadotropin is commonly abbreviated as hCG although it is often referred to simply as chorionic gonadotropin (CG). Measurement of hCG assists in (1) diagnosing and dating pregnancy, (2) identifying ectopic pregnancies and other abnormalities, (3) managing certain neoplasms, and (4) predicting the risk of Down syndrome and trisomy 18.

Chemistry

hCG is a glycoprotein containing a protein core with branched carbohydrate sidechains that usually terminate with sialic acid. T e hormone is a heterodimer composed of two nonidentical, non–covalently bound glycoprotein subunits—alpha (α) and beta (β). When the hCG dimer is dissociated, hormone activity is lost. It has a molecular weight of approximately 37,900 Da and a higher carbohydrate proportion than any other human hormone.

T e hCG carbohydrate composition changes as pregnancy progresses. For example, in the first few weeks of pregnancy, more than 80% of hCG is a large molecular mass (41,000 to 42,000 Da) with additional monosaccharides in its carbohydrate chains called hyperglycosylated hCG (hCG-H). Serum concentrations of hCG-H decline rapidly after the fourth week, and the 37,900 Da molecular mass predominates for the remainder of the pregnancy. In addition to hCG and hCG-H, maternal serum includes numerous other hCG variants. To avoid confusion, the International Federation of Clinical Chemistry and Laboratory Medicine (IFCC) has recommended specific nomenclature for the identification of intact hCG and its variants. T ese include (1) nicked hCG (hCGn), (2) *free α* subunit (hCGα), (3) *free β* subunit (hCGβ), (4) nicked *free β* subunit (hCGβn), and (5) *β core fragment* (hCGβcf). T e variant hCGn is produced from enzymatic cleavage of peptide bonds in hCGβ at position 44-45 (and, after prolonged incubation, at position 51-52) and is biologically inactive. T e variant hCGβcf is the terminal degradation product of hCGβ and represents the 73 amino acid core of hCGβ. It is detected only in urine.

Biochemistry

T e hCG hormone is synthesized in the syncytiotrophoblast cells of the placenta. Minute amounts may also be made by the pituitary glands of older men and women. A single gene located on chromosome 6 encodes the α subunit of all four glycoprotein hormones (TSH, LH, FSH, and hCG). Chromosome 19 contains a family of seven genes that encode the hCGβ subunit, although only three appear to be active. Separate messenger RNAs are transcribed from the respective genes, and the α and β subunits are translated from each. T e subunits spontaneously combine in the rough endoplasmic reticulum and are continuously secreted into the maternal circulation.

Physiology

Physiologically, hCG stimulates the corpus luteum in the ovary to synthesize progesterone during the first weeks of pregnancy. T e placenta makes inadequate amounts of progesterone during this time. No specific receptor for hCG is known; it binds to and activates the LH receptor in cells of the corpus luteum in the maternal ovary.

Methods

Measurement of hCG assists in (1) diagnosing and dating pregnancy, (2) identifying ectopic pregnancies and other abnormalities, (3) managing certain neoplasms, and (4) predicting the risk of Down syndrome and trisomy 18. Many assay techniques have been used to detect and/or measure hCG with immunoassay being the basis for the methods of choice and both qualitative and quantitative types are available.

Qualitative Methods

Numerous home (over-the-counter) kits or point-of-care (POC) devices are available for the qualitative detection of hCG in urine or serum and are widely used for the rapid identification of pregnancy. T ese methods for the qualitative detection of hCG in urine have been granted "**CLIA waived test**" status. T ese tests are designed to employ methodologies that are "so simple and accurate as to render the likelihood of erroneous results negligible." Consequently, they have found widespread applications in situations where a formally trained laboratorian is not available, such as at home and POC environments.

Regarding the latter application, POC devices are single-use methods that utilize immunochromatography for the rapid qualitative detection of hCG when its concentration exceeds a detection threshold, frequently 10 to 25 IU/L. Because qualitative hCG tests are used only for the detection of pregnancy, they are often designed to detect dimeric hCG using a combination of anti-hCG*α* and anti-hCG*β* antibodies. However, the methods incorporated into some devices are designed to detect nondimeric hCG variants. First-morning specimens are preferred for qualitative POC urine pregnancy tests because they are the most concentrated.

Quantitative Methods

All commonly used quantitative hCG methods are immunometric assays designed to measure hCG over a wide range of concentrations. Upper limits of detection vary from 400 to 15,000 IU/L, and specimen dilution is frequently required to obtain an absolute measurement. T e lowest detectable concentration of these assays varies from 1 to 2 IU/L.

Quantitative measurement of hCG is complicated by its molecular heterogeneity. Consequently, considerable variation in measured hCG concentrations is observed between the different methods due to the use of different antibody pairs in different hCG assays. For example, antibodies to hCG will recognize epitopes on the α subunit, the β subunit, or the αβ heterodimer, and consequently, analytical specificity is dependent on the specific pair of antibodies utilized. Another source of variation is the reference material used to calibrate hCG assays. Most hCG assays are calibrated against a World Health Organization (WHO) International Standard, which contains purified urinary hCG with an activity value determined by bioassay.[15] However, these materials also contain substantial amounts of hCGn and hCGβ which is problematic in that some hCG assays over- or under-recognize these variants or may not detect them at all. As a result, hCG assays currently lack harmonization and results from different hCG assays are not the same and cannot be directly compared.

CG measurements in early pregnancy generally are expressed as international units per liter (IU/L). A typical hCG concentration at 16 weeks is approximately 30,000 IU/L, and many laboratories express hCG concentrations in international units per milliliter (e.g., 30,000 IU/L is expressed as 30

IU/mL) (see Figure 44-2). A simple alternative is to use kilo-international units per liter, consistent with the international system for SI units, in which concentrations are expressed per liter.

Serum is used for quantitative hCG assays and is obtained from fasting or non-fasting women by standard phlebotomy techniques. When so collected, hCG is stable in maternal serum and can be shipped at ambient temperature and stored at 4 to 8 °C for 1 week. If testing is to be delayed beyond 1 week, serum should be stored at −20 °C.

Alpha Fetoprotein

The measurement of AFP in maternal serum and amniotic fluid is useful for detecting some serious fetal anomalies (see Table 44-3). For example, maternal serum AFP is elevated in 85% to 95% of cases of fetal open neural tube defects and is low in cases of fetal Down syndrome and trisomy 18. AFP measurement in nonpregnant patients may be used for monitoring certain cancers.

Chemistry

AFP is a glycoprotein having a molecular mass of ~70,000 Da and is synthesized from a gene on chromosome 4. The protein is composed of carbohydrate and a single polypeptide chain containing 591 amino acids. The carbohydrate composition varies depending on the organ of synthesis, the length of gestation, and the source of the specimen (fetal serum vs. amniotic fluid).

Biochemistry

AFP is produced initially by the fetal yolk sac in small quantities, and then by the fetal liver in larger quantities as the yolk sac degenerates. Trace amounts are also produced in the fetal gut and kidneys. Maximal concentration in fetal serum (~3 million µg/L) is reached at about 9 weeks gestation. The concentration then declines steadily to about 20,000 µg/L at term. The increase and decrease in concentration of AFP in the amniotic fluid roughly parallel those in the fetal serum, but the concentration is two to three orders of magnitude lower (~15,000 µg/L at 16 weeks gestation). Amniotic fluid AFP has been measured as early as 8 weeks. It rapidly decreases to its lowest point at 11 weeks, then increases to reach a second maximum at 13 weeks. The concentration then falls in a log-linear fashion until 25 weeks when the decline steepens.

In maternal serum, AFP is first detectable (~5 µg/L) at about the 10th week of gestation. The concentration increases about 15% per week to a peak of approximately 180 µg/L at 25 weeks. The concentration in maternal serum then subsequently declines slowly until term. After birth, the maternal serum AFP rapidly decreases to less than 2 µg/L. In an infant, serum AFP declines exponentially to reach adult concentrations by the 10th month of life. Factors that affect the concentration of AFP in maternal serum include (1) gestational age, (2) maternal weight, (3) the presence of insulin-dependent maternal diabetes mellitus, (4) maternal race, (5) the number of fetuses present, (6) fetal renal disorders that cause proteinuria, and (7) fetal structural anomalies.

Methods

Several commercial immunometric methods are available for the measurement of the concentration of AFP in body fluids. For example, AFP is measured in amniotic fluid using the same immunoassays as for maternal serum AFP after a suitable dilution (usually 1:50 to 1:200). Although two essentially equivalent international reference materials (WHO Reference Preparation for AFP [72-225] and British Standard [72-227]) calibrated in international units are available, most laboratories in the United States report AFP in nanograms per milliliter (micrograms per liter). The relationship between nanograms and international units usually is given as 1.21 ng = 1 IU, but conversion factors may vary by manufacturer, perhaps reflecting differences in the carbohydrate content of respective calibrators.

Serum specimens to be assayed for AFP are obtained from non-fasting women through standard phlebotomy techniques. AFP is very stable in maternal serum and can be shipped at ambient temperature and stored at 4 to 8 °C for 1 week or at −20 °C for years.

AFP in amniotic fluid is less stable than in serum, and leaving samples at room temperature for prolonged periods results in degradation of amniotic fluid AFP. As refrigeration of amniotic fluid compromises chromosome analysis, a portion of the collected fluid should be placed in the refrigerator as soon as possible after collection. Samples sent to reference laboratories should be shipped for next day delivery at ambient temperature or on ice packs if the outside temperature is high. The presence of fetal blood in amniotic fluid samples has been known to increase AFP results, and laboratories should note the presence of blood on the report. In the event of an increased amniotic fluid AFP result (usually >2.0 or 2.5 MoM), the laboratory should test for the presence of fetal blood. Laboratories that measure amniotic fluid AFP need to establish medians for each week between 13 and 25 weeks gestation.

Unconjugated Estriol

In current practice, measurement of urinary and serum estriol (E_3) is no longer recommended for the assessment of fetal well-being.[4] As a replacement, measurement of unconjugated estriol (uE_3) is now used routinely by most U.S. laboratories that provide screening for Down syndrome. This steroid, rather than total estriol (unconjugated plus conjugated estriol), is the most specific of the estrogens for identifying a fetus with Down syndrome.

Any disruption in its biosynthetic pathway will lead to very low concentrations of maternal serum uE_3. Conditions that cause disruption include (1) fetal anencephaly, (2) placental sulfatase deficiency, (3) fetal death, (4) chromosome abnormalities, (5) **molar pregnancy**, and (6) **Smith-Lemli-Opitz syndrome (SLOS)**. Placental sulfatase deficiency presents in the infant as X-linked ichthyosis (thick, scaly skin). It occurs in approximately 1 in every 2000 males. Because of the lack of uE_3, the mother often has delayed onset of labor, and the cesarean section rate is significantly higher in these mothers. SLOS is a serious, rare birth defect that is the result of an inborn error in cholesterol metabolism. Down syndrome leads to a modest

decrease in uE_3. Molar pregnancy is an abnormal pregnancy that is caused by abnormal proliferation of placental tissue in the uterus. It is classified as a gestational trophoblastic disease that grows into a mass in the uterus that has swollen chorionic villi that resemble grapes.

Chemistry

E_3 is an estrogen with hydroxyl groups at positions 3, 16, and 17 (see Chapter 43). Although present in nonpregnant patients in very low concentrations, during late pregnancy this estrogen predominates. Only a minor amount (□10%) of the hormone circulates in plasma unconjugated and, because of its low solubility, this form is strongly bound to SHBG. The majority of E_3 exists as conjugates of glucuronate and sulfate. Conjugation occurs in the maternal liver, makes the hormone more soluble, and thus permits renal clearance.

Biochemistry

E_3 is produced in very large amounts during the last trimester of pregnancy. The biosynthetic pathway requires the (1) fetal adrenal gland, (2) fetal liver, and (3) placenta to be fully functioning. The fetal adrenal cortex possesses a unique zone for the production of steroids. The fetal adrenal avidly binds low-density lipoprotein to take in cholesterol, which is converted to two major steroid intermediates: pregnenolone sulfate and dehydroepiandrosterone sulfate (DHEA-S). The fetal liver, possessing 16α-hydroxylase, converts DHEA-S to 16α-hydroxy-DHEA-S, and finally, the placenta uses fetal 16α-hydroxy-DHEA-S to synthesize E_3. Approximately 90% of maternal serum E_3 is derived from this pathway. A minor amount is made using precursors from the maternal ovary. Concentrations typical for the second trimester of pregnancy are 0.70 to 2.50 μg/L, depending on the assay used.

Methods

Determination of uE_3 is difficult because of its low concentration. Nonisotopic, automated immunometric methods are commercially available. They are calibrated by the use of chemically pure E_3. E_3 values are reported in mass units (nanograms per milliliter or micrograms per liter) or SI units (nanomoles per liter). The equation for converting mass to SI units is:

$$1\ \text{ng/mL} \times 3.47 = 3.47\ \text{nmol/L}$$

Maternal serum specimens are obtained from fasting or nonfasting women by standard phlebotomy techniques. However, uE_3 is relatively unstable and the procedures for the (1) collection, (2) storage, and (3) shipment of maternal serum specimens need to be rigorously adhered to. For example, the uE_3 concentration increases in blood at room temperature and at 4 °C, because the conjugated forms are able to spontaneously deconjugate to form the parent hormone. Therefore collected blood should be allowed to clot, and then serum should be removed promptly. uE_3 is stable in serum for up to 7 days at 2 to 4 °C.

Inhibin A

In addition to the utility of inhibin A as a predictor of Down syndrome risk as discussed previously, inhibin A and B measurements have applications in (1) ovarian cancer monitoring, (2) disorders of ovulation, and (3) early detection of viable pregnancy following IVF.

Chemistry

Inhibins are proteins consisting of dimers of dissimilar subunits (α and β) linked by disulfide bridges. The β subunit occurs in two closely related forms (β_A and β_B), leading to two types of dimeric inhibin (inhibin A, $\alpha\beta_A$, and inhibin B, $\alpha\beta_B$). The mature form of inhibin, which has a molecular mass of approximately 32,000 Da, is produced by cleavage of larger precursor forms. Another group of related molecules, the activins, are dimers consisting of just the β subunits. InhA is the only form within the inbibin/activin family of proteins that provides sufficient discrimination to be useful in Down syndrome screening.

Biochemistry

Inhibins are members of the transforming growth factor-β (TGFβ) superfamily of proteins. They and their closely related activins are proteins that suppress or stimulate FSH secretion, respectively. In the reproductive system, inhibin and activin subunits are expressed in the (1) placenta, (2) granulosa cells of the ovary, and (3) Sertoli cells of the testis. InhA and inhibin B have distinctive serum profiles during the human menstrual cycle. InhA peaks in the luteal phase of the cycle, whereas inhibin B is maximal in serum during the mid-follicular phase with a peak at ovulation. In postmenopausal women, the concentrations of both forms of inhibin are non-detectable.

InhA is produced by the fetoplacental unit beginning in early pregnancy. InhA concentrations exhibit a complex pattern during the course of pregnancy, rising to a peak at 8 to 10 weeks gestation, declining to a minimum at 17 weeks, and then resuming to slowly increase to term. Unlike the other screening tests, average inhibin concentrations change relatively little from 15 to 20 weeks gestation. Typical values in the second trimester of pregnancy range from 50 to 400 ng/L with levels at 17 weeks gestation reaching a nadir of about175 ng/L.

Methods

Highly specific methods for measuring inhibins are available. Serum specimens to be assayed for inhibins are obtained from non-fasting women by standard phlebotomy techniques. InhA is stable in maternal serum with shipment at ambient temperature and storage at 4 to 8 °C for 1 week.

Pregnancy-Associated Plasma Protein A

Low concentrations of PAPP-A early in pregnancy have been associated with (1) Down syndrome, (2) a high rate of fetal loss, (3) poor fetal growth (intrauterine growth retardation), (4) premature delivery, (5) hypertension, and (6) preeclampsia.

Chemistry

PAPP-A is a zinc-containing metalloproteinase glycoprotein. Its gene is found on chromosome 9. It is translated into a 1,626 amino acid product, of which 1,546 amino acids compose the mature protein. Circulating PAPP-A is part of a larger

molecular complex that includes two subunits of PAPP-A covalently bound to two subunits of a protein called the "pro major basic protein (pro MBP)", forming a heterotetramer. The PAPP-A complex has a molecular mass of about 500 kDa.

Biochemistry

PAPP-A is expressed at low concentrations in many tissues, but high amounts of PAPP-A protein and mRNA are localized to placental tissues throughout gestation. PAPP-A immunoreactivity is found in syncytiotrophoblast cells.

Concentrations of maternal serum PAPP-A increase as gestation proceeds to term (Figure 44-5). These are critical to normal fetal growth because of its role as an insulin-like growth factor binding protein (IGFBP) protease. It regulates the action of **insulin-like growth factor** (II IGF-II) and predominantly cleaves IGFBP-4.

Methods

PAPP-A immunoassays are commercially available in the United States, in both manual and automated formats. However, their use is currently restricted for research use only. Serum specimens to be assayed for PAPP-A are obtained from fasting and non-fasting women by standard phlebotomy techniques. A small increase in PAPP-A concentrations has been reported for collection in plastic versus glass tubes. PAPP-A concentrations are stable in serum at 4 °C for 1 week or longer, depending on the assay used for testing.

Fetal Fibronectin

The concentration of fFN in cervical and vaginal secretions was proposed in 1991 as a test to aid in predicting preterm delivery.

Biochemistry

Fibronectin is a term for a family of ubiquitous adhesive glycoproteins that cross-link to collagen to bind cells together. These proteins are found on cell surfaces and in plasma and amniotic fluid. The fetus has a unique fibronectin that is defined by a monoclonal antibody, FDC-6. When labor begins and cellular adhesion between the placenta and the uterine wall is disrupted, the concentration of fFN in cervical and vaginal secretions increases. Mothers with more than 50 ng/mL (50 μg/L) of fFN in these secretions during the second and third trimesters have a higher risk for preterm delivery, whereas those below that cutoff are at decreased risk. A majority of patients with results greater than 50 ng/mL will, however, repair any placental disruption and successfully continue the pregnancy.

Figure 44-5 Typical median values for maternal serum pregnancy-associated plasma protein A (closed black circles) and total human chorionic gonadotropin (open red circles) in the first trimester. The observed average gestational age is plotted on the horizontal axis, and the median of that week's PAPP-A or total hCG measurements is plotted on the vertical axis.

Method

In one commercial method, fFN is measured using a membrane immunoassay, which has a solid phase polyclonal goat anti-fFN antibody and an enzyme-labeled monoclonal anti-fFN. The specimen to be assayed for fFN is obtained by collecting cervical or vaginal mucus with a Dacron polyester swab. The fully saturated swab contains approximately 150 μL of fluid. The swab is placed into 750 μL of buffer. An aliquot of the diluted specimen is added to the cassette containing the antibodies and color development is measured and related to the concentration of fFN.

Placental Alpha Microglobulin-1

Placental alpha microglobulin-1 (PAMG-1) is a placental glycoprotein secreted into the amniotic fluid during pregnancy. Its concentration in amniotic fluid is 400 to 1,000 times greater than in maternal blood and up to 40,000 times greater than in cervicovaginal fluid with intact membranes. A test for PAMG-1 that exploits these large differences in concentration has been developed for clinical use as an aid for the detection of PROM.

A rapid immunochromatographic method is commercially that utilizes two monoclonal antibodies for the rapid detection of PAMG-1 in cervicovaginal fluid. The specimen is collected using a polyester swab that is placed into the vagina for 1 minute. The fluid obtained is eluted off the swab by rinsing it in a vial containing a buffer solution for 1 minute. After standing in buffer for 10 minutes, the test result is determined by visual inspection of a test and a control line on the lateral flow device. The analytical limit of detection of the test is 5 ng/mL.

This test is highly sensitive and specific for the detection of PROM. False-positive results may be caused by contamination of the specimen with large amounts of blood. False-negative results may occur if the specimen is collected 12 or more hours after a rupture that is subsequently obstructed by the fetus or is resealed.

Amniotic Fluid Bilirubin

The presence of bilirubin in amniotic fluid is an indicator of fetal erythroblastosis. As the concentration of bilirubin in amniotic fluid is generally too low (□0.01 to 0.03 mg/dL) to be measured by standard photometric techniques, a direct spectrophotometric method is used. The test is referred to as the ΔA_{450} test. In this procedure, the difference in the direct absorbance measured between 365 and 550 nm of an amniotic fluid is used to prepare a calibration curve. To interpret

the results obtained with this method, the gestational age of the fetus must be known as the amount of bilirubin present in amniotic fluid changes with gestational age.

Tests for Evaluating Fetal Lung Maturity[7]

Historically, FLM tests have been used to determine whether the best perinatal survival will be achieved in utero or in the nursery. Common situations in which FLM testing is requested include (1) before repeat cesarean delivery when the age of gestation is uncertain, (2) preterm labor, (3) PROM, (4) worsening maternal hypertension, (5) severe renal disease, (6) intrauterine growth retardation, or (7) fetal distress.[2]

Standards of Laboratory Practice

Several standards of laboratory practice for FLM testing have been published.[4,6] They contain recommendations regarding (1) specimen collection, (2) handling, (3) centrifugation, and (4) mixing that remain valid today. These recommendations include (1) assessment of FLM should be conducted prior to a delivery at less than 39 weeks gestation, (2) FLM tests should be selected based on sample quality, (3) hospital laboratories should offer a rapid FLM test in their laboratory or from a reference laboratory, (4) rapid FLM tests should be available daily on both a routine and emergency basis, and (5) laboratories should communicate the results of any FLM test immediately to the ordering location.

Collection and Handling of Amniotic Fluid Specimens for Fetal Lung Maturity Assessment

Amniotic fluid is obtained by transabdominal amniocentesis (see Chapter 6). In a multifetal pregnancy, there are usually separate sacs, each of which should be sampled. Vaginal pool specimens are rarely adequate for testing.

Whenever possible, the fluid should be tested immediately. If there is to be a delay of a few hours, the fluid should be refrigerated at 4 °C. The total phospholipid content of amniotic fluid does not change significantly during at least a week of storage, and lamellar bodies are stable for at least 30 days. It should be noted that a single freeze-thaw cycle decreases the **lamellar body count (LBC)**. Immediately before the fluid is tested, it should be gently inverted several times to obtain a uniform suspension.

Tests Used to Assess Fetal Lung Maturity

Tests used to assess FLM include measurement of (1) LBC, (2) PG content, and (3) Lecithin/Sphingomyelin (L/S) ratio.

Counting of Lamellar Bodies

Lamellar bodies have been counted directly using the platelet channel of whole blood cell counters. This test is termed the lamellar body count (LBC).

When counting lamellar bodies, the procedural step of centrifugation of the amniotic fluid sample is omitted. Also, mixing of the fluid is critical to obtain a homogenous suspension prior to testing. Because of different platelet identification algorithms, counts will be lower or higher on different instruments. Instruments that use similar techniques to count the platelets (e.g., impedance) will show greater concordance than those that use different techniques.

Specimens containing mucus produce erratic results. In addition, contamination of the fluid with whole blood will decrease the LBC by presumably trapping them in a fibrin matrix. Contamination with even small amounts of meconium will produce dramatic increases in the LBC.

Clinical outcomes studies have reported that LBC has high clinical sensitivity (95% to 100%) but low clinical specificity (about 70%) for prediction of RDS.

Determination of Lecithin and Lecithin/Sphingomyelin Ratio

Chemically, lecithin is palmitate disaturated-phosphatidylcholine (DSPC). It is the major surfactant found in the lung representing 85% of total lecithins in the body.[4] Its concentration in amniotic fluid tends to rise with increasing gestational age. The concentration of lecithin in amniotic fluid is measured directly and is correlated with FLM, or its concentration is related to another lipid, sphingomyelin, and that ratio used to predict lung maturity. This L/S ratio tends to rise with increasing gestational age. This is not a uniform gradual increase; a rather sudden increase occurs at 34 to 36 weeks gestation and correlates with the development of FLM.

A conservative reference interval for lung maturity is an L/S ratio of 2.5 or greater. About 1% of babies delivered within 24 hours of obtaining an L/S ratio greater than 2.5 are expected to develop RDS. Almost half of infants with L/S ratios between 1.5 and 2.5, however, will not develop RDS.

Measurement of Phosphatidylglycerol

The detection of PG is a commonly used qualitative method used to assess FLM. Measurement of PG was classically performed in conjunction with the L/S ratio, and the combination of the two tests is known as the lung profile. The rapid detection of PG is typically accomplished using a commercially available immunochemical test.

The concentration of PG in amniotic fluid increases with gestational age. Most thin-layer chromatography (TLC) techniques are positive when PG exceeds about 2 μmol/L. At this cutoff, results indicating maturity are almost always correct, but results indicating immaturity are frequently incorrect.

Review Questions

1. The most severe form of hemolytic disease of the newborn (HDN) is referred to as
   a. respiratory distress syndrome (RDS).
   b. ectopic pregnancy.
   c. jaundice.
   d. erythroblastosis fetalis.
2. In a developing fetus, the major blood-forming organ until 24 weeks gestation is the
   a. bone marrow.
   b. liver.
   c. lung.
   d. kidney.

3. The trophoblast cells that surround the developing blastocyst
   a. form the amnion and amniotic fluid.
   b. synthesize glucose for the fetus.
   c. are the major blood-forming organs in early fetal life.
   d. invade the endometrium and form the placenta.
4. The composition of amniotic fluid is most typically like that of which one of the following?
   a. Extracellular fluid
   b. Intracellular fluid
   c. Cerebrospinal fluid
   d. Blood
5. Hemolytic disease of the newborn (HDN) is caused by
   a. lack of folic acid in the maternal diet.
   b. increased formation of fetal hemoglobin (Hb F).
   c. maternal antibodies against fetal erythrocytes.
   d. blockage of placental transfer of immunoglobulin A (IgA) antibodies.
6. Which one of the following fetal disorders has been demonstrated to be caused by low folic acid intake during pregnancy?
   a. Neural tube defects
   b. Trisomy 18
   c. Renal atresia
   d. Respiratory distress
7. Which of the following hormones is (are) synthesized by the placenta?
   a. Chorionic gonadotropin (CG)
   b. Estriol (E_3)
   c. Progesterone
   d. All of the above are synthesized by the placenta.
8. The process of identifying pregnancies at sufficiently high risk of a serious birth defect, such as Down syndrome, to warrant invasive diagnostic testing is referred to as
   a. presymptomatic testing.
   b. prenatal screening.
   c. identity testing.
   d. karyotype analysis.
9. The majority of waste produced by a fetus is in the amniotic fluid. Which one of the following structures is responsible for removal of this waste from the amniotic fluid?
   a. Fetal kidneys
   b. Fetal liver
   c. Fetal lungs
   d. Placenta
10. When a fertilized egg implants in a location other than the body of the uterus, the condition is called
    a. Down syndrome.
    b. spina bifida.
    c. ectopic pregnancy.
    d. hyperemesis gravidarum.

CHAPTER

45 Newborn Screening and Inborn Errors of Metabolism*

Marzia Pasquali, Ph.D., F.A.C.M.G., and Nicola Longo, M.D., Ph.D., F.A.C.M.G

Objectives

1. Define the following:
   - Aminoacidopathy
   - Fatty acid oxidation disorder
   - Inborn error of metabolism (IEM)
   - Multiplex analysis
   - Newborn screening
   - Organic acidemia
   - Second-tier testing
   - Tandem mass spectrometry (MS/MS)
   - Urea cycle disorder
2. Define and describe autosomal recessive inheritance patterns including significance of this pattern in inborn errors of metabolism (IEMs), percent risk of having an affected child in each pregnancy, percent chance of having a carrier and percent chance of having an unaffected child; diagram an autosomal recessive inheritance pattern pedigree.
3. List the six components of a newborn screening program; state the criteria required of any newborn screening program.
4. Discuss the American College of Medical Genetics and Genomics (ACMG) uniform screening panel of newborn screening tests, including classifications and names of disorders.
5. State the three classes of metabolic disorders, and list an example of each class; list five disorders of amino acid metabolism, three disorders of fatty acid metabolism, and three disorders of carbohydrate metabolism.
6. For the following disorders, list causes and symptoms, treatments, available screening, and second-tier laboratory analyses and results of them:
   - Alkaptonuria
   - Galactosemia
   - Glutaric acidemia type I
   - Glycine encephalopathy
   - Homocystinuria
   - Maple syrup urine disease (MSUD)
   - Medium-chain acyl-CoA dehydrogenase (MCAD) deficiency
   - Phenylketonuria (PKU)
   - Tyrosinemia
   - Urea cycle disorders
7. State the principle of tandem mass spectrometry (MS/MS) and how the results of this screening analysis are interpreted with regard to inborn errors of metabolism (IEMs); state an advantage of using this type of analysis.
8. Discuss the issue of false positive results in newborn screening, including tests most commonly misinterpreted and the use and principle of second-tier tests.
9. List four types of confirmatory laboratory tests used to verify borderline newborn screening test results.
10. Analyze and solve case studies related to inborn errors of metabolism (IEMs), newborn screening, and laboratory testing related to them.

Key Words and Definitions

Alkaptonuria A genetic disorder due to deficiency of the enzyme homogentisic acid (HGA) dioxygenase.

Aminoacidopathy Any one of group of inborn errors of amino acid metabolism caused by (1) defective activity of an enzyme in the metabolic pathway of one or more amino acids or (2) a defect in a protein needed for transport of an amino acid into or out of cells; usually detected by the presence of increased concentrations of one or more amino acids in blood or urine or both.

Argininosuccinate lyase (ASL) deficiency A genetic disorder that affects the body's ability to clear the nitrogen already incorporated into the urea cycle as argininosuccinate. This disorder often presents with rapid-onset hyperammonemia in the newborn period. Also known as argininosuccinic aciduria.

Argininosuccinate synthetase (ASS) deficiency A genetic disorder characterized by a deficiency of argininosuccininate and an increase in the ammonia concentration in the blood. Also known as citrullinemia type I.

Autosomal recessive disorder A disorder characterized by the requirement that both copies of a gene are abnormal (see following definition for autosomal recessive inheritance).

Autosomal recessive inheritance A Mendelian inheritance pattern in which (1) nonsex chromosomes (autosomes) carry a DNA sequence (gene) for the inherited trait and (2) two copies of the DNA sequence must be present for the trait to appear in an individual; heterozygous parents have a 25% chance of having an affected offspring.

*The authors gratefully acknowledge the contributions of Dr. Barbara Sawyer to the previous edition of this chapter on which portions of this chapter are based.

Key Words and Definitions—cont'd

Citrullinemia type II An autosomal recessive disease characterized by increased concentrations of citrulline in serum and urine. Ammonia intoxication is another manifestation. This disorder is characterized by neuropsychiatric symptoms, including abnormal behaviors, loss of memory, seizures, and coma.

Dihydropteridine reductase (DHPR) An enzyme that catalyzes the reversible formation of tetrahydrobiopterin (BH_4) from dihydrobiopterine; deficiency of BH_4 results in malignant hyperphenylalaninemia.

Disorders of amino acid metabolism A group of disorders of amino acid metabolism caused by defective activity of an enzyme leading to increased amino acids in blood (and urine).

Disorders of carbohydrate metabolism A group of disorders caused by loss of an enzyme in the metabolic pathway of a carbohydrate, leading to increased concentrations of that carbohydrate in blood or its accumulation within organs and tissues.

Disorders of fatty acid oxidation A group of disorders caused by deficiency of an enzyme in the oxidation pathway of fatty acids, leading to inability to use fat as an energy source.

Dried blood spot (DBS) A form of biosampling where blood samples are blotted and dried on filter paper.

Galactosemia An inherited disease in which the transformation of galactose to glucose is blocked, allowing galactose to increase to toxic concentrations in the body.

Glucose-6-phosphate dehydrogenase (G-6-PD) deficiency An X-linked recessive hereditary disease characterized by abnormally low quantities of the enzyme G-6-PD involved in the pentose phosphate pathway, especially important in red blood cell metabolism.

Glutaric acidemia type I (GAI) An inherited disorder in which an affected individual is unable to completely metabolize (1) lysine, (2) hydroxylysine, and (3) tryptophan. Excessive quantities of glutaric acid (GA) and related compounds accumulate and damage the brain.

Glycogen storage diseases Genetic diseases, also known as glycogenoses, that involve the enzymes regulating glycogen accumulation and breakdown.

Guthrie test A semiquantitative microbiological assay for the determination of amino acids in blood or urine.

Homocystinuria A condition characterized by the excretion of excess homocystine in the urine; this biochemical abnormality has a variety of autosomal recessive genetic causes as well as nongenetic causes.

Hyperornithinemia-Hyperammonemia-Homocitrullinuria (HHH) syndrome An autosomal recessive syndrome characterized by increased plasma concentrations of ornithine, postprandial hyperammonemia and homocitrullinuria, and aversion to protein ingestion; the affected gene codes for the mitochondrial ornithine transporter, ornithine translocase.

Inborn error of metabolism (IEM) Inherited disorder due to deficiency of an enzyme or transporter impairing the transformation of body chemicals.

Isovaleric academia A metabolic disorder which disrupts or prevents normal metabolism of the branched-chain amino acid leucine. It is characterized by acidosis, coma, and an unpleasant body odor.

Long-chain 3-hydroxyacyl-CoA dehydrogenase (LCHAD) deficiency A metabolic disease characterized by defective fatty acid oxidation due to a defect in an enzyme in the β-oxidation pathway.

Maple syrup urine disease (MSUD) An autosomal recessive metabolic disorder affecting branched-chain amino acids (leucine, isoleucine, and valine). The urine of affected individuals smells like maple syrup.

Marfan syndrome A congenital disorder of connective tissue characterized by long limbs and casued by abnormal fibrillin metabolism; it affects various structures, notably heart valves and aorta.

Medium-chain acyl-CoA dehydrogenase (MCAD) deficiency A disorder of fatty acid oxidation that impairs the body's ability to break down medium-chain fatty acids into acetyl-CoA

Methylmalonic acidemia An autosomal recessive metabolic disorder resulting from defects in the metabolic pathway in which methylmalonyl-coenzyme A (CoA) is converted into succinyl-CoA by the enzyme methylmalonyl-CoA mutase.

Microcephaly A condition characterized by an abnormally small head circumference; associated with a small brain (microencephaly).

Multiplex analysis Simultaneous assessment of multiple analytes in a single sample.

Nonketotic hyperglycinemia (NKHG) A usually fatal autosomal-recessive aminoacidopathy with accumulation of glycine in body fuids, particularly the blood, urine, and cerebrospinal fuid.

Ochronosis A condition characterized by an accumulation of dark pigment in cartilage and other connective tissue that indicates alkaptonuria or phenol poisoning.

Organic acidemia A disorder of intermediary metabolism in which lack of an enzyme leads to buildup of an organic acid (from deamination of the amino acid) as opposed to the buildup of the parent amino acid.

Ornithine translocase deficiency Ornithine translocase transports ornithine into the liver where it enters the urea cycle. When ornithine translocase is deficient, the concentration of ornithine and ammonia increases in the blood.

Phenylketonuria (PKU) A disorder characterized by the accumulation of phenylalanine in blood that results from the absence of phenylalanine hydroxylase activity leading to production of phenylketones that are excreted in urine.

Propionic acidemia An organic acid disorder due to deficiency of an enzyme involved in amino acid and fatty acid catabolism. It is characterized by excess of propionic acid in the blood and urine,

Tandem mass spectrometry (MS/MS) A spectrometric method of analysis where two mass spectrometers are connected in series. It involves separation and identification of substances and chemicals based on their mass to charge (m/z) ratio.

Tyrosinemia A genetic disorder involving the metabolism of the tyrosine. Affected individuals have high concentrations of tyrosine in blood (hypertyrosinemia) and urine (tyrosinuria).

Urea cycle disorder Any disorder in which the body is unable to excrete waste nitrogen–ammonia, resulting in mental and behavioral dysfunction, coma, and death.

Inborn errors of metabolism (IEM) are genetically determined biochemical disorders affecting an individual's ability to convert nutrients or to use them for energy production. They are caused by the impaired function of (1) enzymes, (2) transporters, or (3) cofactors and result in accumulation of abnormal metabolites (substrates) proximal to the metabolic block or by lack of necessary products (path A to D, Figure 45-1). Abnormal by-products can also be generated when alternative pathways are used to dispose of the excess metabolites (path A to F, Figure 45-1).

Typically, IEMs present in the newborn period or in infancy. Some diseases, however, such as fatty acid oxidation defects or milder variants of classic metabolic disorders, may not be detected until adulthood. Despite the long asymptomatic period, their consequences are still devastating and may result in death. Therefore, it is critical to identify and treat these diseases before irreversible damage occurs. The frequency of individual diseases is rare, varying from 1:10,000 to 1:200,000 or even rarer. Their cumulative frequency, however, is substantial and approaches a frequency of 1:2,000.

Inheritance Pattern of Metabolic Disorders

Metabolic disorders are caused by mutations in genes that code for specific enzymes or transporters involved in metabolic pathways. The majority of metabolic disorders have **autosomal recessive inheritance,** in which affected individuals have a mutation in both alleles encoding for a specific enzyme or transporter (Figure 45-2). Because the mutation is in a gene on a nonsex chromosome (autosome), girls are affected as often as boys. In most cases, the parents of children with one of these metabolic conditions are carriers of the condition, that is, they carry one normal allele and one mutant allele, and they do not show clinical signs of the condition. In each singleton pregnancy when both parents are carriers, there is (1) a 25% chance that the child is affected, (2) a 50% chance that the child is a carrier like the parents, and (3) a 25% chance that the child has two normal alleles (Figure 45-2).

Clinical Presentation of Metabolic Disorders

The medical consequences of IEMs vary from failure to thrive to acute illness leading in some cases to (1) brain damage, (2) coma, and (3) death. In many cases the acute presentation is preceded by a symptom-free period that is variable in length depending on the specific disease. In most cases, there is a treatment available for these disorders consisting of special diets (formulas) that do not contain the specific nutrients that the patients are unable to metabolize. The treatment is effective if begun early before symptoms occur, but damage that has already occurred is usually irreversible. Thus, the ideal time for identifying patients with metabolic disorders is at birth or earlier.

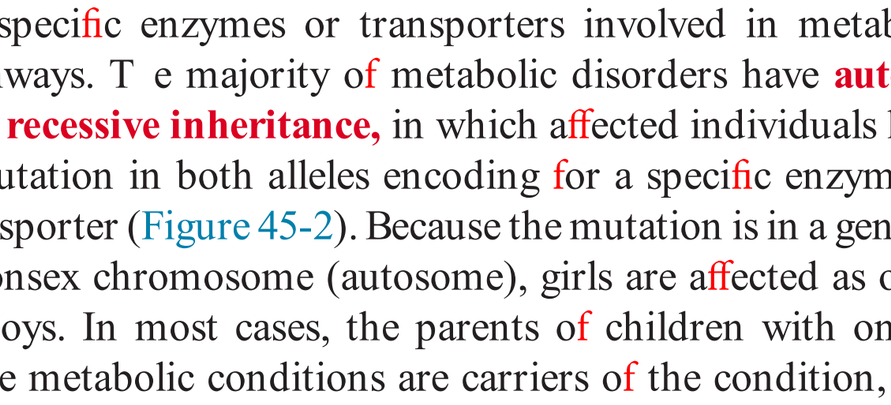

Figure 45-1 Schematic of metabolic pathway. The substrate A is converted by a series of reactions into product D. If one of the enzymes (arrows) is defective (metabolic block), the substrate of the reaction will accumulate (A in this case) and can enter alternative pathways of metabolism, leading to the formation of byproducts (E and F in this case). At the same time, the concentration of the product of the reaction (D) will decrease.

Biochemical Diagnosis

The biochemical diagnosis of IEMs and treatment monitoring involve analysis of (1) metabolites, (2) enzymatic activity, and/or (3) DNA sequence. Because of technological advances (such as, the introduction of **tandem mass spectrometry (MS/MS)**, allowing the simultaneous detection of multiple analytes), many IEMs are now included in newborn screening programs.

Newborn Screening

Newborn screening is a public health activity aimed at early identification of conditions for which timely intervention is expected to result in elimination or reduction of (1) morbidity, (2) mortality, and (3) disabilities.

Background

Newborn screening was originally instituted in the 1960s as a result of the pioneering efforts of Robert Guthrie and his colleagues, who developed a screening assay (known as the **Guthrie test**) for measuring the phenylalanine content of a **dried blood spot (DBS)** on filter paper collected from the blood of newborn babies.[5,6]

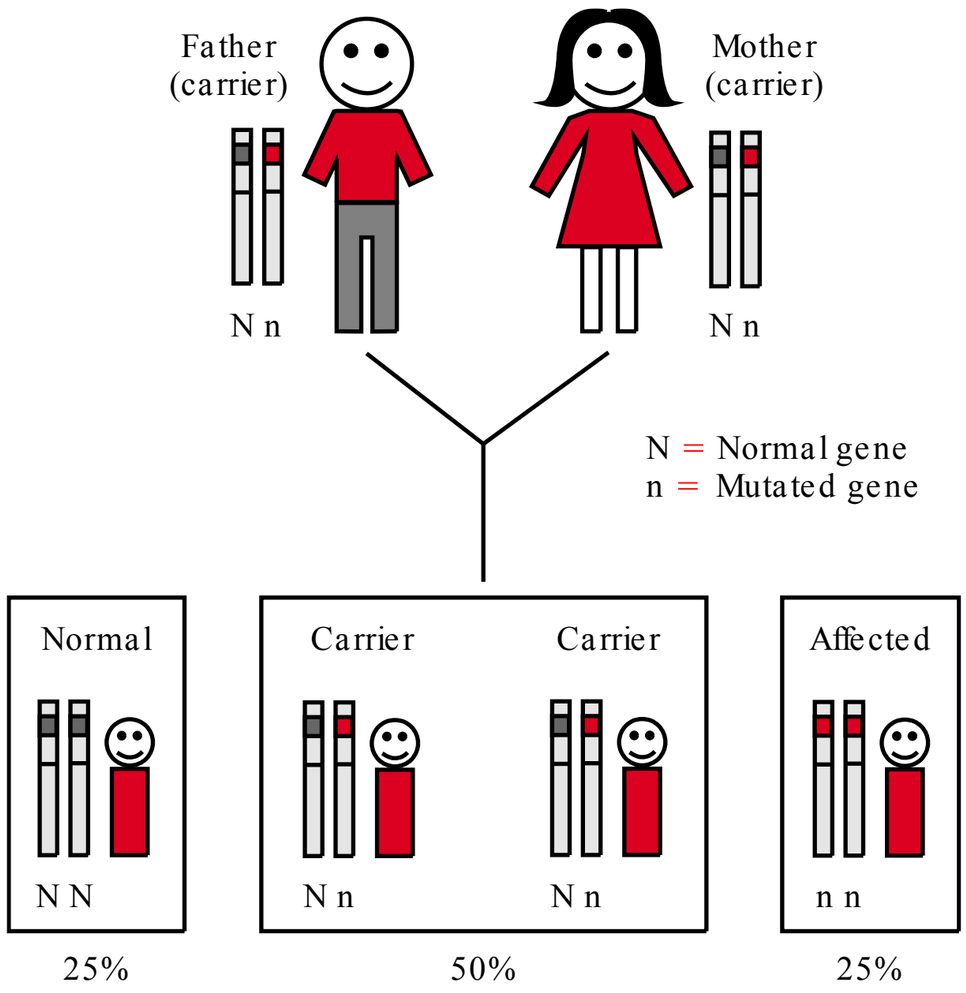

Figure 45-2 Autosomal recessive inheritance pattern.

Criteria of Newborn Screening Programs

Newborn screening tests must fit specific criteria that evaluate the (1) characteristics of the disease, (2) test used to screen for it, and (3) newborn screening program. The disease to be screened must (1) be serious, (2) be fairly common, (3) have a natural history that is understood, and (4) have helpful treatment or genetic counselling (in the case of genetic disease) available. In addition, the screening test must be (1) acceptable to the public, (2) reliable, (3) valid, and (4) affordable. The newborn screening program requires the availability of expedient diagnosis and treatment of the disease and effective communication of results. Newborn screening programs must be effectual public health approaches to the diagnosis of treatable disorders early in life. Because newborn screening is a program, its efficacy depends on the integration and collaboration among its different components, involving (1) organizations of public health, (2) screening and diagnostic laboratories, (3) physicians, and (4) families of affected children.

Steps to be Followed in a Newborn Screening Program

The different steps that need to be coordinated and tracked in a newborn screening program are:

1. Screening (sample collection and delivery, laboratory testing)
2. Follow-up (complete demographic information, satisfactory specimens, abnormal screening results)
3. Diagnosis (confirmatory tests, clinical consultation)
4. Clinical management (medical home, specialist physician, genetic counselor, dietitian)
5. Education (healthcare professionals, parents)
6. Quality assurance: analytical (proficiency testing, quality controls, standards), efficiency of follow-up system, efficacy of treatment, long-term outcome

Each of these components should have specifically-written protocols that deal directly with the performance of the tasks involved. To assist laboratories in writing such protocols and procedures, the Clinical and Laboratory Standards Institute has published guidelines for newborn Screening, including guidelines on (1) blood collection on filter paper (LA 4-A5/new code NBS01-A6), (2) laboratory testing by tandem mass spectrometry (NBS04-A), (3) follow-up activities (I/LA27-A/new code NBS02-A6), and (4) document preparation (QMS02-A6). These documents describe the basic principles, scope, and range of activities within a newborn screening program and how to prepare the prerequisite documents. They are available at http://www.clsi.org/; (accessed December 31. 2013).

Second-Tier Testing

One of the major pitfalls in newborn screening is the number of false-positive results associated with certain screening tests. To reduce the number of infants requiring additional confirmatory testing, second-tier tests have been developed. These second-tier tests involve further analysis of the same blood spot that produced an abnormal result targeting different, more specific analytes and, often, using a methodology different from the one used in the primary screening test. They include (1) DNA analysis for cystic fibrosis[10] (see Chapter 24), (2) MS/MS steroid profiling for congenital adrenal hyperplasia[11] (see Chapter 41), and (3) other biochemical tests, such as thyroid stimulating hormone for congenital hypothyroidism[8] (see Chapter 42). Second-tier testing has become a crucial component of newborn screening programs to increase the sensitivity and the specificity of the screening test.

Although metabolic disorders identified by MS/MS represent the largest group of diseases identifiable by newborn screening, more traditional screening methods can identify other IEMs and endocrine and hematologic disorders such as, (1) **galactosemia**, (2) biotinidase deficiency, (3) cystic fibrosis, (4) congenital hypothyroidism, (5) congenital adrenal hyperplasia, (6) hemoglobinopathies, and (7) severe combined immunodeficiency. Such tests include (1) enzyme assays, (2) immunoassays, (3) electrophoresis, and (4) DNA tests. Advances in therapeutic interventions for IEMs are continuously expanding the role of newborn screening. Of note, newborn screening does not identify all metabolic disorders, and some patients are missed. Therefore a symptomatic patient, at any age, should be investigated despite normal newborn screening results.

Inborn Errors of Metabolism

In this section, disorders of metabolism of (1) amino acids, (2) fats, and (3) carbohydrates are discussed in general, with selected individual disorders of each class reviewed in more detail as examples. An online database containing a catalog of human genetic disorders is found at www.ncbi.nlm.nih.gov/omim/ (accessed December 31, 2013. This database is entitled "Online Mendelian Inheritance in Man" (OMIM) and is a comprehensive and authoritative compendium of human genes and genetic phenotypes. In this database, individual disorders are assigned a specific OMIM number.

Disorders of Amino Acid Metabolism

Disorders of amino acid metabolism collectively affect approximately 1 in 8000 newborns. Almost all are transmitted as autosomal recessive traits and result from a lack of a specific enzyme in the metabolic pathway of an amino acid. This is leads either to the accumulation of (1) the parent amino acid, (2) its by-products or (3) the catabolic products (organic acids), depending on the location of the enzyme block. Disorders of amino acid metabolism are divided into two groups: (1) **aminoacidopathies**, in which the parent amino acid accumulates in excess in blood and spills over into urine; and (2) **organic acidemias**, in which products in the catabolic pathway of certain amino acids accumulate.

An example of an aminoacidopathy is **phenylketonuria (PKU)**, a disorder of phenylalanine metabolism caused in the majority of cases by deficiency of phenylalanine hydroxylase, the enzyme responsible for the conversion of phenylalanine to tyrosine. Other examples include (1) **maple syrup urine disease (MSUD)**, (2) **homocystinuria**, and (3) **tyrosinemia**.

Glutaric acidemia type I is an example of an organic acidemia that is a disorder of lysine and tryptophan metabolism. Others include (1) **isovaleric acidemia**, (2) **methylmalonic acidemia**, and (3) **propionic acidemia** (Table 45-1).

TABLE 45-1 Uniform Screening Panel recommended for every Newborn Screening Program by the American College of Medical Genetics and Genomics: Core Conditions*

		Metabolic Disorder					
ACMG Code	Core Condition	Organic Acid Condition	Fatty Acid Oxidation Disorders	Amino Acid Disorders	Endocrine Disorder	Hemoglobin Disorder	Other Disorder
PROP	Propionic acidemia	X					
MUT	Methylmalonic acidemia (methylmalonyl-CoA mutase)	X					
Cbl A,B	Methylmalonic acidemia (cobalamin disorders)	X					
IVA	Isovaleric acidemia	X					
3-MCC	3-Methylcrotonyl-CoA carboxylase deficiency	X					
HMG	3-Hydroxy-3-methyglutaric aciduria	X					
MCD	Holocarboxylase synthase deficiency	X					
βKT	β-Ketothiolase deficiency	X					
GAI	Glutaric acidemia type I	X					
CUD	Carnitine uptake defect (carnitine transport defect)		X				
MCAD	Medium-chain acyl-CoA dehydrogenase deficiency		X				
VLCAD	Very long-chain acyl-CoA dehydrogenase deficiency		X				
LCHAD	Long-chain 3-hydroxyacyl-CoA dehydrogenase deficiency		X				
TFP	Trifunctional protein deficiency		X				
ASA	Argininosuccinic aciduria			X			
CIT	Citrullinemia type I			X			
MSUD	Maple syrup urine disease			X			
HCY	Homocystinuria			X			
PKU	Phenylketonuria			X			
TYR-I	Tyrosinemia type I			X			
CH	Congenital hypothyroidism				X		
CAH	Congenital adrenal hyperplasia				X		
Hb SS	S,S disease (Sickle cell anemia)					X	
Hb S/βTh	S, βeta-thalassemia					X	
Hb S/C	S,C disease					X	
BIOT	Biotinidase deficiency						X
CCHD	Critical congenital heart disease						X
CF	Cystic fibrosis						X
GALT	Galactosemia						X
HEAR	Hearing loss						X
SCID	Severe combined immunodeficiences						X

*The nomenclature for conditions is based on data from reference 12.[12]

ACMG, American College of Medical Genetics and Genomics.

Modified from American College of Medical Genetics and Genomics. Newborn screening: towards a uniform screening panel and system. Genetic Med 2006;8(5) Suppl:S12-S252.

The clinical manifestations of the organic acidemias vary from no observable clinical consequences to neonatal mortality. Conditions, such as (1) developmental retardation, (2) seizures, (3) alterations in sensorium, or (4) behavioral disturbances, occur in more than half the disorders. Metabolic ketoacidosis, often accompanied by hyperammonemia, is a frequent finding in organic acidemias. The compound(s) accumulated depend on the (1) site of the enzymatic block, (2) reversibility of the reactions proximal to the lesion, and (3) availability of alternative pathways of metabolic "runoff."

Phenylketonuria

PKU (OMIM #261600) is a disorder of phenylalanine metabolism that results from the absence of phenylalanine hydroxylase activity leading to the accumulation of phenylalanine and production of phenylketones that are excreted in urine.

Phenylalanine is an essential amino acid, constituting 4% to 6% of all dietary protein. Phenylalanine that is not used in protein synthesis is converted to tyrosine by the enzyme phenylalanine hydroxylase and further degraded via a ketogenic pathway (Figure 45-3). The frequency of hyperphenylalaninemia/PKU is 1:10,000 to 1:20,000 live births. The majority (98%) of cases of PKU are caused by mutations in the phenylalanine hydroxylase gene with the remaining 2% being caused by defects in biosynthesis or recycling of tetrahydrobiopterin (BH_4), the cofactor for phenylalanine hydroxylase.

Primary or secondary (due to a deficiency of the cofactor) impairment of phenylalanine hydroxylase causes (1) increased phenylalanine, (2) increased phenylketones, (3) increased phenylamines, and (4) a deficiency of tyrosine (Figure 45-3). The greatly increased concentration of phenylalanine impairs brain development and function, affecting other organs minimally. Patients with classic PKU are clinically asymptomatic at birth with developmental delays and neurological manifestations typically becoming evident at several months of life when brain damage has already occurred. Untreated PKU patients develop (1) **microcephaly**, (2) eczematous skin rash, (3) "mousy" odor (due to accumulation of phenylacetate), and (4) severe mental retardation. The treatment of PKU includes a diet (1) low in protein and phenylalanine and (2) supplemented with tyrosine, minerals, vitamins, and other nutrients to sustain normal growth. Treatment should be continued for life.

Newborn screening leads to early detection and therapy of patients with PKU with prevention of mental retardation. Ideally, treatment should start before 2 weeks of age. Pregnant women with PKU should adhere to a strictly controlled diet that is low in phenylalanine and proteins, because phenylalanine is teratogenic and results in an increased risk of spontaneous abortions or of having a child with (1) growth retardation, (2) microcephaly, (3) significant developmental delays, and (4) birth defects.

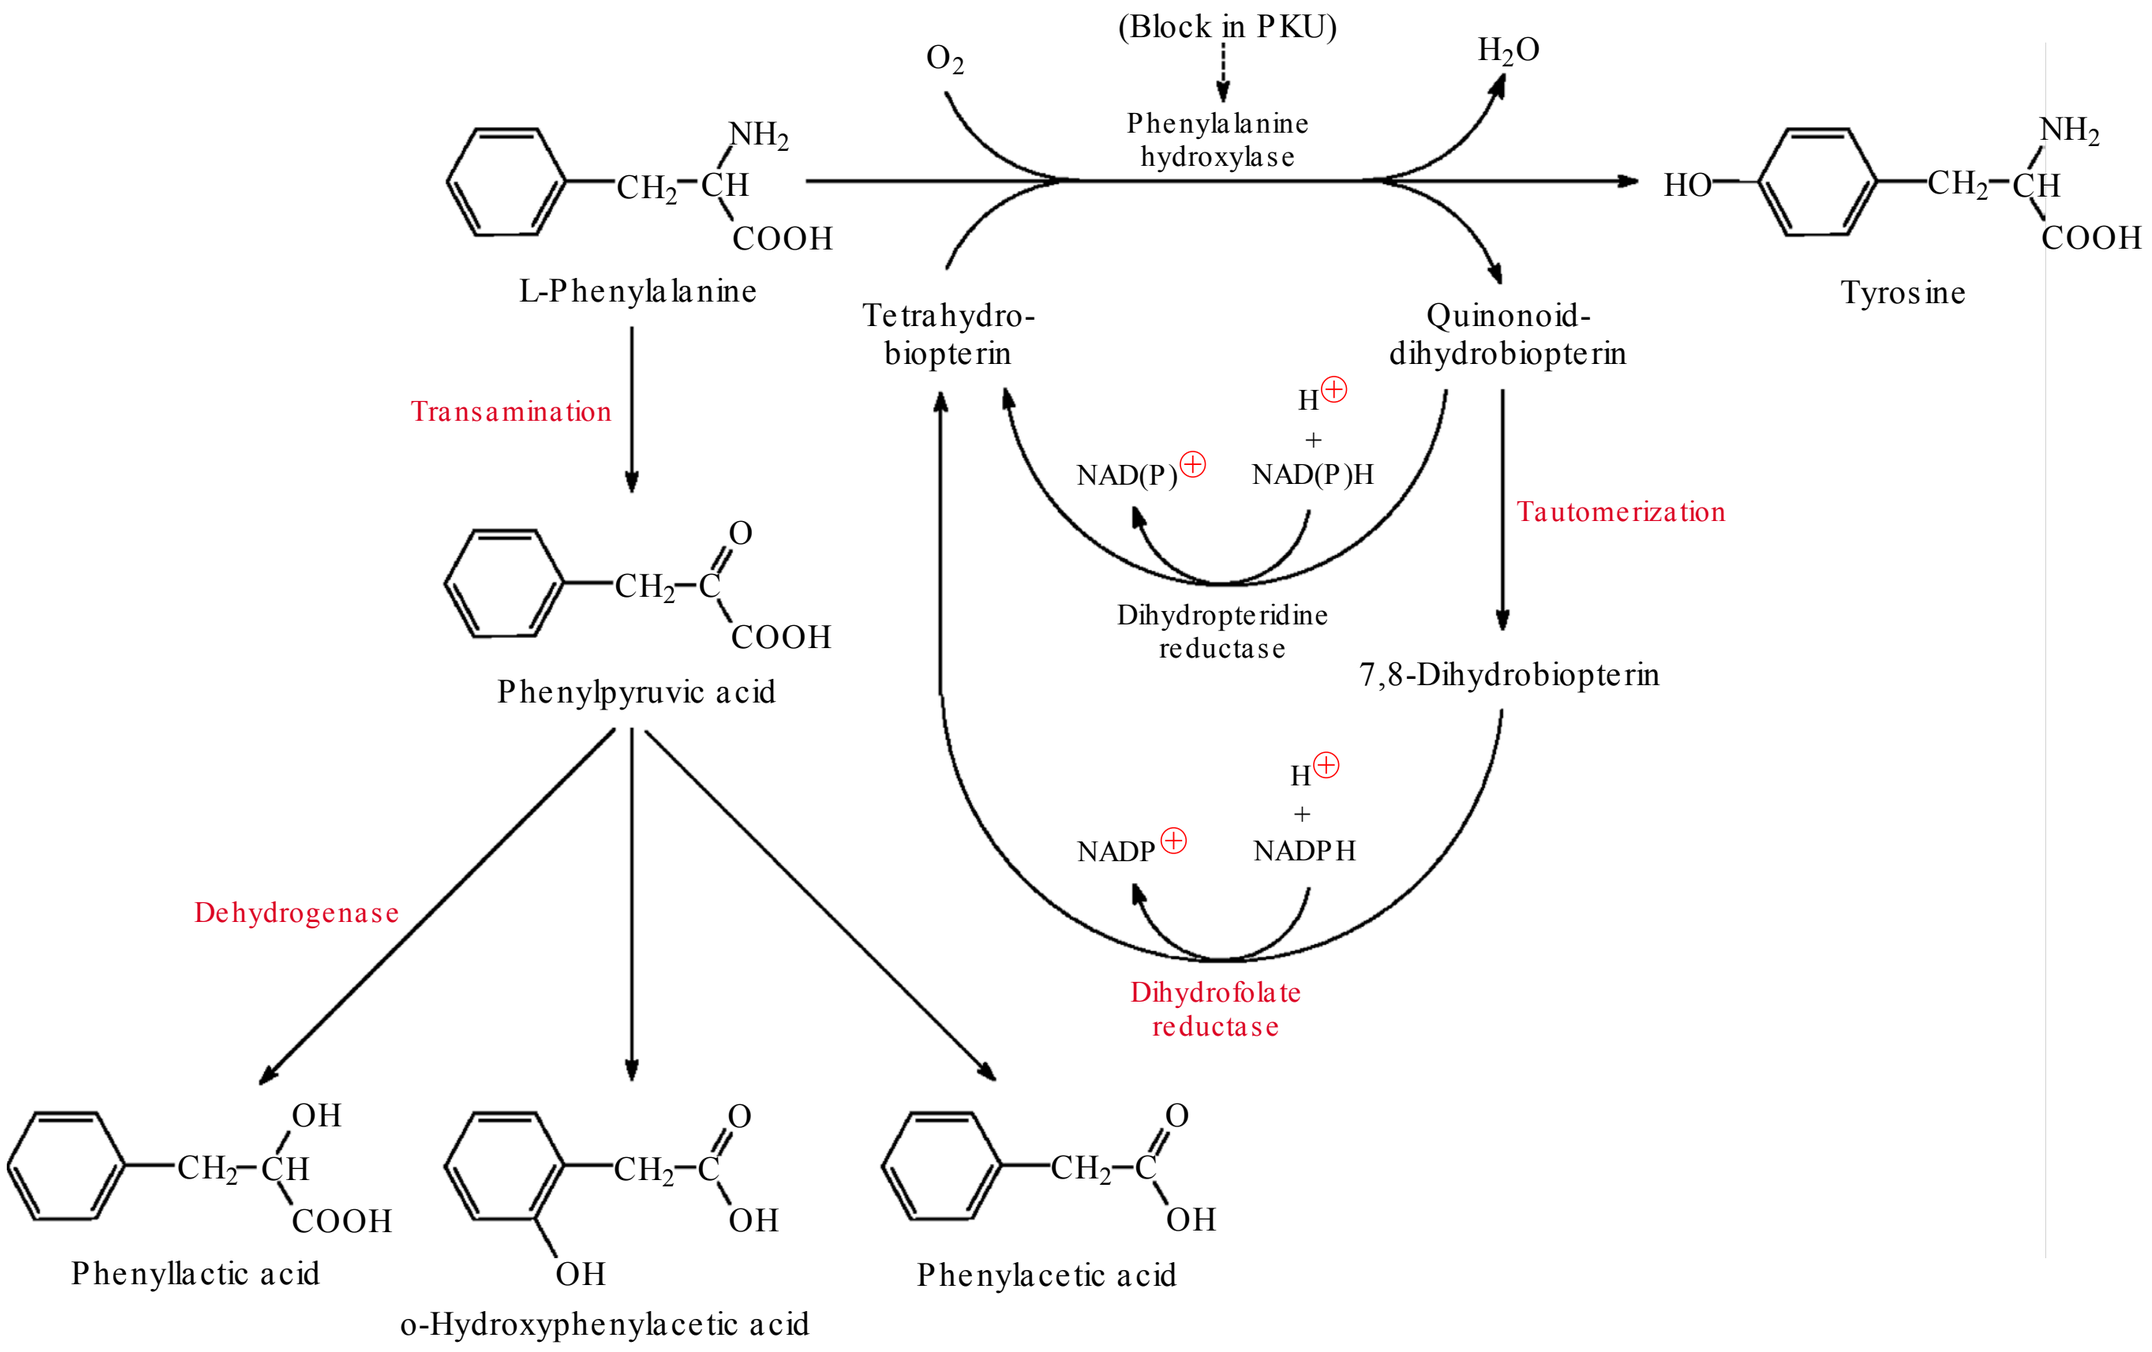

Figure 45-3 Metabolism of phenylalanine and tyrosine.

The diagnosis of PKU is confirmed biochemically by demonstration of increased plasma phenylalanine and an increased phenylalanine:tyrosine ratio. Urine specimens from affected individuals contain increased concentrations of phenylketones (hence the name phenylketonuria). Enzymatic confirmation of phenylalanine hydroxylase deficiency is not usually performed (the enzyme is expressed only in the liver), but mutational analysis of the gene is increasingly used because there is a correlation between severity of the mutation and phenylalanine tolerance. All children with hyperphenylalaninemia should be screened for defects in BH_4 synthesis or recycling. This is performed by measuring the urinary pterin profile and by measuring the enzyme activity of **dihydropteridine reductase (DHPR)** in blood spotted on filter paper. Deficiency of BH_4 affects the synthesis of several neurotransmitters, including dopamine and serotonin, because it is a cofactor of (1) phenylalanine hydroxylase, (2) tyrosine hydroxylase, (3) tryptophan hydroxylase, and (4) nitric oxide synthase. Patients with a defect in BH_4 synthesis or recycling have neurological symptoms and developmental regression in the first few months of life, despite adequate control of phenylalanine intake and plasma concentrations. They can develop seizures and have a characteristic hypotonia of the trunk with hypertonia of the extremities. These patients require therapy with BH_4 and appropriate neurotransmitters. They may or may not require a low phenylalanine diet once BH_4 therapy is initiated.

Tyrosinemia

Tyrosinemia is a genetic disorder characterized by increased blood concentrations of tyrosine. There are three types of tyrosinemia (I-III); each is caused by the deficiency of a different enzyme (Figure 45-4). Tyrosinemia type I (TYR-I) is the most severe form and is caused by a deficiency of fumarylacetoacetate hydrolase. Tyrosinemia type II is caused by a deficiency of tyrosine aminotransferase, and tyrosinemia type III is caused by a deficiency of 4-hydroxyphenylpyruvate dioxygenase.

The incidence of TYR-I is approximately 1 in 100,000 with a clustering of cases in the Lac-St. Jean region of Quebec (Canada). Patients with TYR-I present, usually before 6 months of age, with severe liver involvement, or with (1) chronic failure to thrive, (2) mild hepatocellular dysfunction, (3) renal involvement, and (4) rickets due to renal Fanconi syndrome. They have extreme irritability caused by peripheral neuropathy mimicking acute intermittent porphyria. Untreated patients develop liver cirrhosis and are at very high risk for liver cancer.

Patients with TYR-I have increased concentrations of tyrosine in the plasma, but this increase usually is not as marked as in patients with other forms of tyrosinemia. Increased tyrosine can also be seen in (1) tyrosinemia types II and III, (2) transient tyrosinemia of the newborn, (3) prematurity, (4) liver disease from any cause, (5) mitochondrial DNA depletion syndrome, and (6) diets very rich in proteins. The biochemical diagnosis of TYR-I is based on the detection in urine organic-acid testing of succinylacetone, derived from fumarylacetoacetic acid, the intermediate immediately upstream of the enzyme defect. TYR-1 is identified by newborn screening only when succinylacetone is used as the primary marker, because tyrosine usually is not elevated in the newborn period in these patients. Therapy consists of (1) low dietary tyrosine, (2) low dietary phenylalanine, and (3) drug therapy with 2-(2-nitro-4-trifuoro-methylbenzoyl)-1,3-cyclohexanedione (NTBC), an inhibitor of 4- hydroxyphenylpyruvate dioxygenase (see Figure 45-4). NTBC prevents the synthesis of succinylacetone, which disappears almost immediately from urine organic-acid testing after initiation of treatment. The adequacy of the diet is monitored by measuring the plasma amino acids and urine organic acids which will show disappearance of succinylacetone. Measurement of alpha fetoprotein is also used to monitor these patients, because liver cancer is a complication of this condition. Liver transplantation is indicated in patients who progress to liver failure and in those acquiring liver cancer.

Alkaptonuria

Alkaptonuria is caused by deficiency of the enzyme homogentisic acid (HGA) dioxygenase (see Figure 45-4). Deficiency of this enzyme leads to (1) the presence of HGA and its oxide (called alkapton) in the urine, (2) bluish-black pigmentation in connective tissue (**ochronosis**), (3) arthritis, and (4) urine that turns dark with standing or alkalinization. The accumulation of HGA in tissues causes cartilage damage in their joints, specifically in the spine, leading to low back pain at a young age. The pigment can also accumulate in cardiac valves causing their failure.

Treatments that reduce the complications of alkaptonuria are not available. However, treatment with NTBC prevents formation of homogentisic acid and is being explored as a potential therapy.

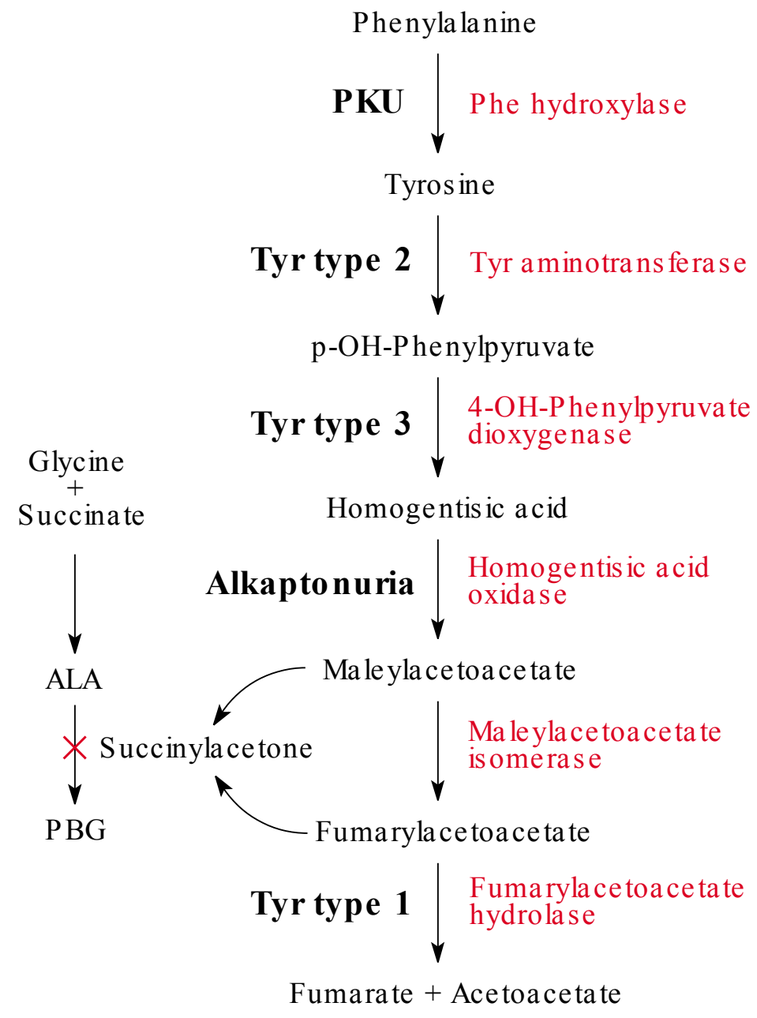

Figure 45-4 Disorders of inborn errors of metabolism (IEMs) resulting from defciency of key enzymes required in the metabolic catabolism of phenylalanine. Specifc disorders are shown in bold letters.

Homocystinuria

Homocystinuria is characterized by increased concentrations of the sulfur-containing amino acid, homocysteine, in blood and urine (Figure 45-5). It is caused by at least seven genetically different disorders. The most common disorder is classic homocystinuria that is caused by reduced activity of cystathionine β-synthase. The worldwide incidence is approximately 1:300,000 live births with a very high incidence in the country of Qatar (1:1800). Clinical manifestations are nonspecific at first and may include failure to thrive and developmental delay. Patients usually develop lens dislocation (often requiring surgery) and a body habitus like that seen in **Marfan syndrome**. (Homocysteine interferes with disulfide formation in fibrillin, the protein defective in Marfan syndrome). Patients whose blood homocysteine concentration continues to increase are at risk of blood clots, which are a life-threatening complication of the condition.

The biochemical diagnosis of homocystinuria is obtained by plasma amino acid analysis showing increased plasma concentrations of methionine (especially in children) and the presence of the disulfide homocystine. Classic homocystinuria is detected in newborn screening by increased concentrations of methionine in whole blood spots. Therapy for classic homocystinuria requires (1) high doses of pyridoxine (the cofactor of cystathionine β-synthase), (2) a special diet low in methionine, and (3) administration of betaine that donates a methyl group to homocysteine to generate methionine.

Maple Syrup Urine Disease

Maple syrup urine disease (MSUD) is an **autosomal recessive disorder** with an incidence of approximately 1:250,000 live births. It is caused by a deficiency of the branched-chain alpha-keto acid dehydrogenase complex (BCKDC), leading to a buildup of the branched-chain amino acids leucine, isoleucine, and valine and their toxic ketoacids in the blood and urine (Figure 45-6). The disease is named for the presence of sweet-smelling urine with an odor similar to that of maple syrup. Several forms of this disease may occur, depending on the gene affected and the severity of the mutations. The enzyme complex consists of four subunits designated $E_1\alpha$, $E_1\beta$,

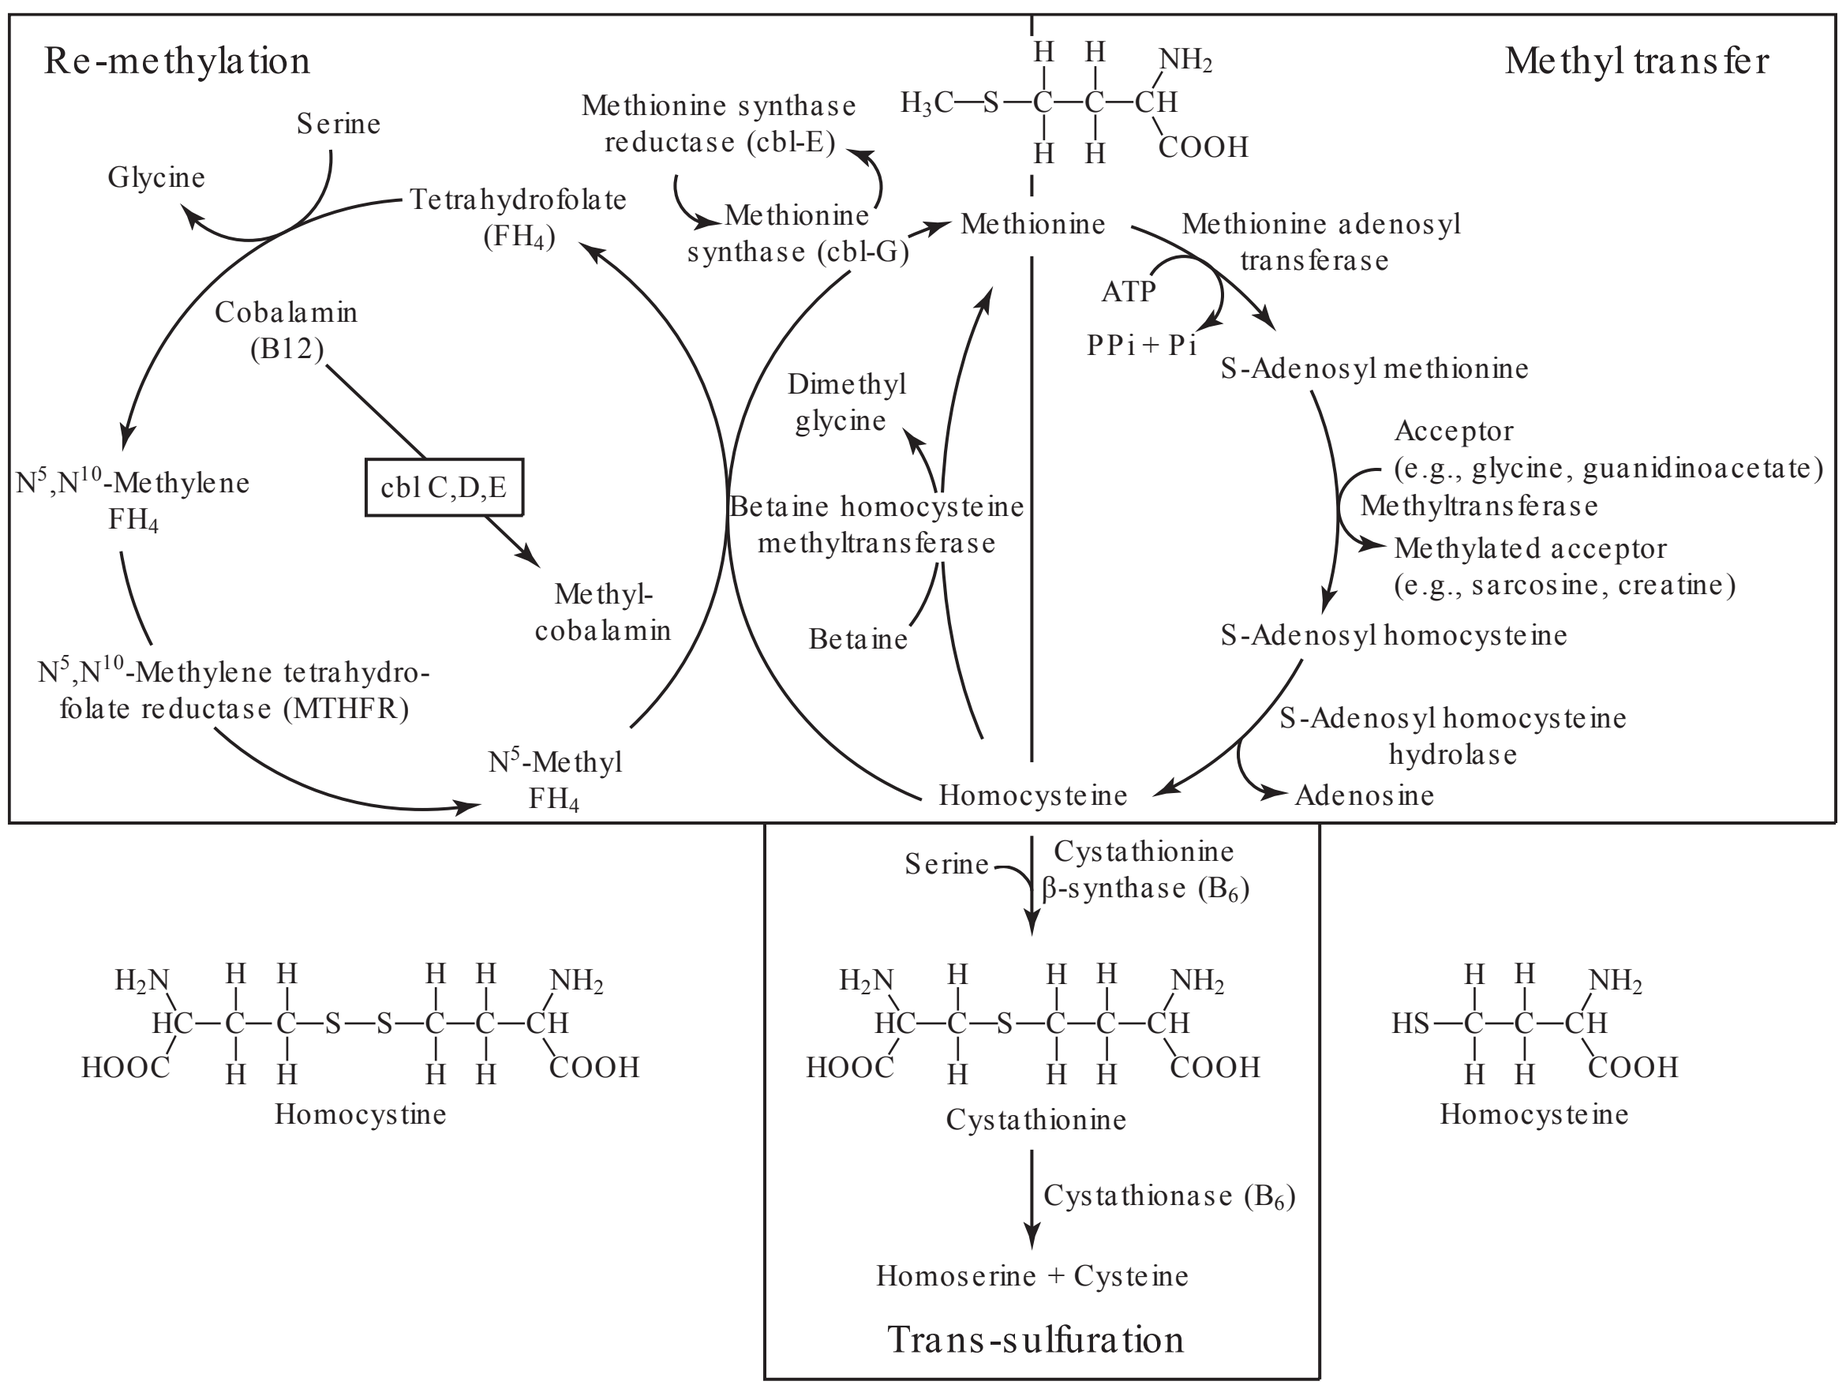

Figure 45-5 Sulfur amino acid metabolism. Methionine transfers a methyl group during its conversion to homocysteine. Defects in methyl transfer or in the subsequent metabolism of homocysteine by the pyridoxal phosphate (vitamin B_6)–dependent cystathionine β-synthase increase plasma methionine concentrations. Homocysteine is transformed into methionine via remethylation. This reaction is catalyzed by methionine synthase and requires methylcobalamin and folic acid. Defciencies in these enzymes or lack of cofactors is associated with decreased or normal methionine concentrations. In an alternative pathway, homocysteine is remethylated by betaine:homocysteine methyl transferase. The chemical structures of homocystine and homocysteine are also shown.

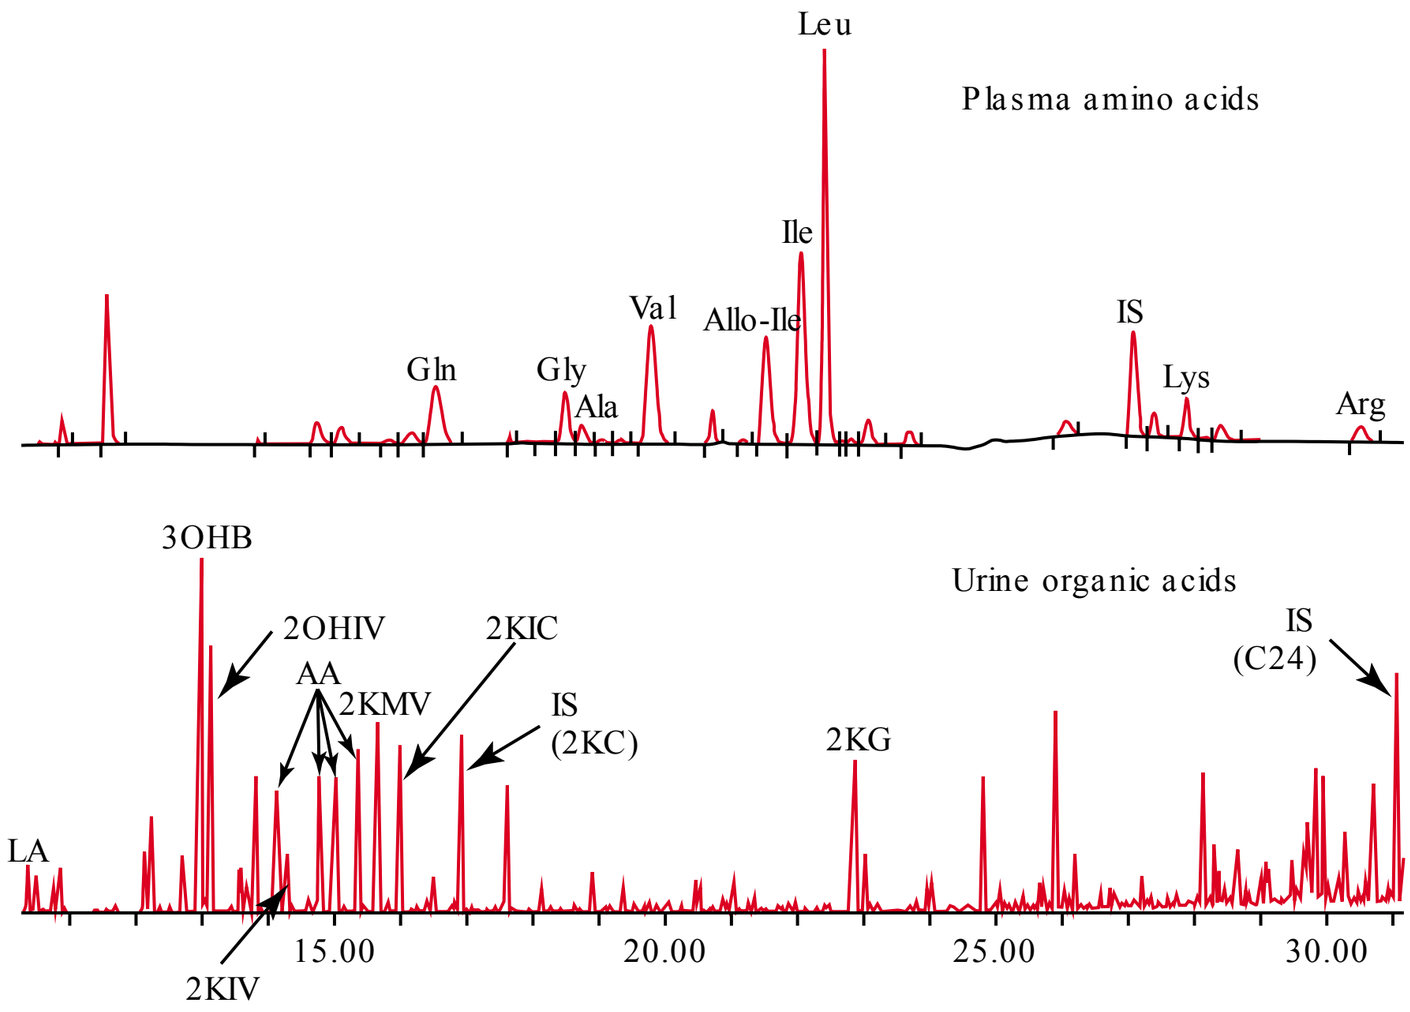

Figure 45-6 Profles of plasma amino acids and urine organic acids in maple syrup urine disease (MSUD) as measured by ion-exchange chromatography and gas chromatography mass spectrometry (GCMS) respectively. Top, All three branched-chain amino acids (leucine, valine, and isoleucine) are increased in MSUD. Alloisoleucine (an amino acid not normally present) is also seen in this condition. Bottom, Urine organic acids show the presence of the characteristic metabolites 2-OH-isovaleric acid (2OHIV), 2-ketoisovaleric acid (2KIV), 2-ketomethylvaleric acid (2KMV), and 2-ketoisocaproic (2KIC). Lactic acid (LA) and ketones (3-OH-butyric acid [3OHB] and acetoacetate [AA]) are also increased in the catabolic state. 2-ketocaproic acid (2KC) and tetracosane (C24) are used as internal standards.

E_2, and E_3. MSUD results from mutations in any of the genes that code for the enzyme subunits.

Individuals with classic MSUD present with poor feeding and vomiting during the first week of life followed by lethargy and coma within a few days. T is usually follows a normal birth and an uneventful first few days of life. Routine laboratory work is mostly unremarkable except for the presence of ketones in urine. Diagnosis is established by measuring plasma amino acids and finding increased branched chain amino acids and the presence of alloisoleucine, which is characteristic of this disease.

Cornerstones of treatment include diets that have a restricted content of branched-chain amino acids and include supplementation with (1) high-dose thiamine and, in many patients, low doses of (2) valine and (3) isoleucine.

Urea Cycle Disorders

A **urea cycle disorder**, or urea cycle defect, is caused by a deficiency of one of the enzymes or a transporter in the urea cycle, which is responsible for removing ammonia from the blood stream. T e urea cycle involves a series of biochemical steps in which nitrogen derived from protein metabolism is removed from the blood and converted to urea, which is then excreted in urine. In urea cycle disorders, the nitrogen accumulates in the form of ammonia, a toxic substance, and is not removed from the body.

Urea cycle disorders can result in (1) mental and behavioral dysfunction, (2) coma, and (3) death. T e urea cycle disposes of the nitrogen groups of amino acids before their carbon skeleton is metabolized to gluconeogenic (most amino acids) or ketogenic precursors (leucine and lysine), or both (isoleucine, phenylalanine, tyrosine, and tryptophan). T is cycle requires the combined action of different enzymes and mitochondrial transporters (Figure 45-7). Deficiency of any of these enzymes or transporters impairs the function of the urea cycle, causing hyperammonemia.

Newborn screening can identify **argininosuccinate synthetase def ciency** (ASS deficiency **or citrullinemia type I**), **citrullinemia type II** (mitochondrial aspartate transporter/citrin deficiency), **argininosuccinate lyase (ASL) def ciency**, and arginase deficiency. Increased ornithine and homocitrulline, theoretically, are the markers for the syndrome of **hyperammonemia-hyperornithinemia-homocitrullinuria syndrome (HHH) syndrome** (also known as **ornithine translocase def ciency**). Patients with urea cycle defects may have symptoms at any age. In the neonatal period, there is usually a brief interval between birth and clinical manifestations with the most severe cases having symptoms before the results of newborn screening are available. Hyperammonemia and the accumulation of glutamine in the brain lead to (1) poor feeding, (2) vomiting, (3) lethargy, or (4) irritability progressing to coma and death.

Diagnosis is accomplished by measuring plasma amino acids and identifying the compound present in excess. Patients are treated by a diet low in proteins and administration of nitrogen scavengers, such as sodium benzoate and phenylacetate, which bind and remove glycine and glutamine, respectively.

Glycine Encephalopathy (Nonketotic Hyperglycinemia)

Glycine encephalopathy, or **nonketotic hyperglycinemia (NKHG)**, is a severe condition caused, in most cases, by a defect in the P, T, and H proteins of the glycine cleavage system. Patients with the classic form of the disease have symptoms within the first days of life with (1) lethargy, (2) poor suckling, (3) severe hypotonia, (4) hiccups, (5) seizures, and (6) apnea. Most of these patients die in the first few months of life or survive with profound developmental delays. Atypical

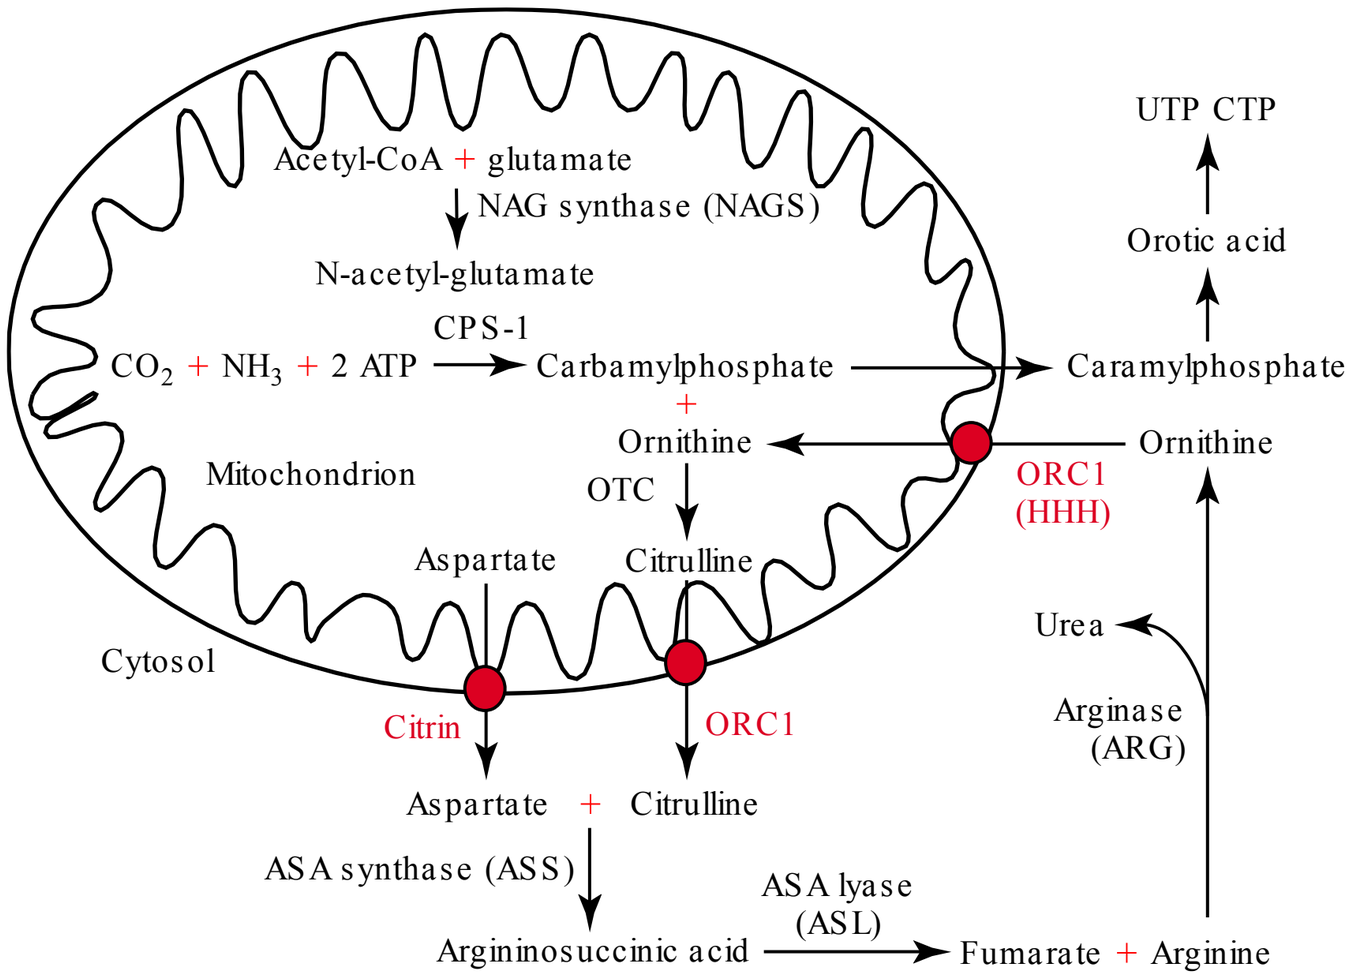

Figure 45-7 The urea cycle. In this cycle, urea is formed starting from ammonia (NH_3). It requires several enzymes and mitochondrial transporters, any of which can be defective and may impair the function of the urea cycle. ASL, Argininosuccinate lyase; ASS, argininosuccinate synthase; ARG, arginase; citrin, aspartate/glutamate exchanger; CP, carbamylphosphate; CPS-1, carbamyl phosphate synthase 1; CTP, cytidine triphosphate; NAGS, N-acetylglutamate synthase; ORC1, ornithine/citrulline mitochondrial transporter; OTC, ornithine transcarbamylase; UTP, uridine triphosphate.

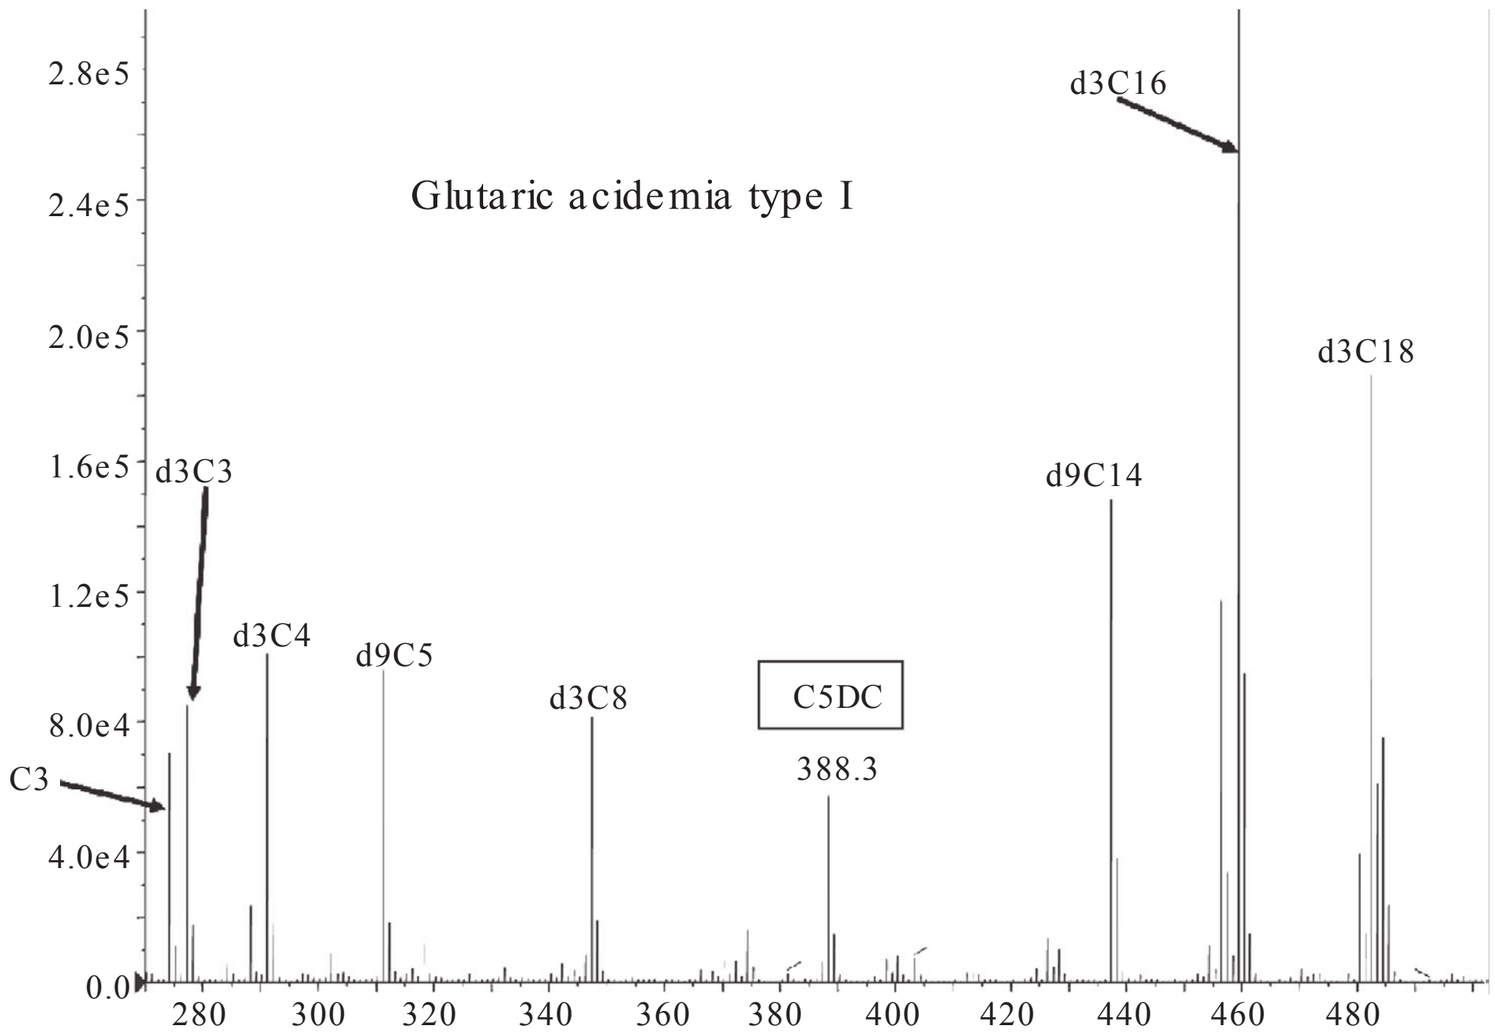

Figure 45-8 Acylcarnitine profle (by tandem mass spectrometry [MS/MS]) in glutaric acidemia type I (GAI). Glutaryl (C5-DC)-carnitine is the diagnostic metabolite in GAI. Internal standards (deuterated) are indicated by the number of deuterium atoms (d) and the length of the carbon chain (C) attached to carnitine.

variants of NKHG have been diagnosed in patients with rather disparate manifestations who have in common, in most cases, seizures and delays of different degrees of severity.

Glutaric Acidemia Type I

Glutaric acidemia type I (GAI) (OMIM #231670) is an autosomal recessive disorder of the metabolism of (1) lysine, (2) hydroxylysine, and (3) tryptophan; it is caused by deficiency of glutaryl-CoA dehydrogenase. In this condition, glutaric acid (GA) and 3-hydroxyglutaric acid (3-OH-GA), formed in the catabolic pathway of the earlier amino acids, accumulate especially in urine. Affected patients have brain atrophy and macrocephaly (head circumference often increases dramatically following birth), and they can develop acute dystonia secondary to degeneration of the corpus striatum (a component of the motor system in the brain). In most cases this is triggered by an infection, with fever, between 6 and 18 months of age.[6]

GAI is identified by an increased concentration of glutarylcarnitine (C5DC) on newborn screening (Figure 45-8). The diagnosis is biochemically confirmed by urine organic acid analysis that indicates the presence of excess 3-OH-GA, and the urine acylcarnitine profile shows glutarylcarnitine as the major peak. Therapy consists of (1) carnitine supplementation to remove GA, (2) a diet restricted in amino acids capable of producing GA, and (3) prompt administration of

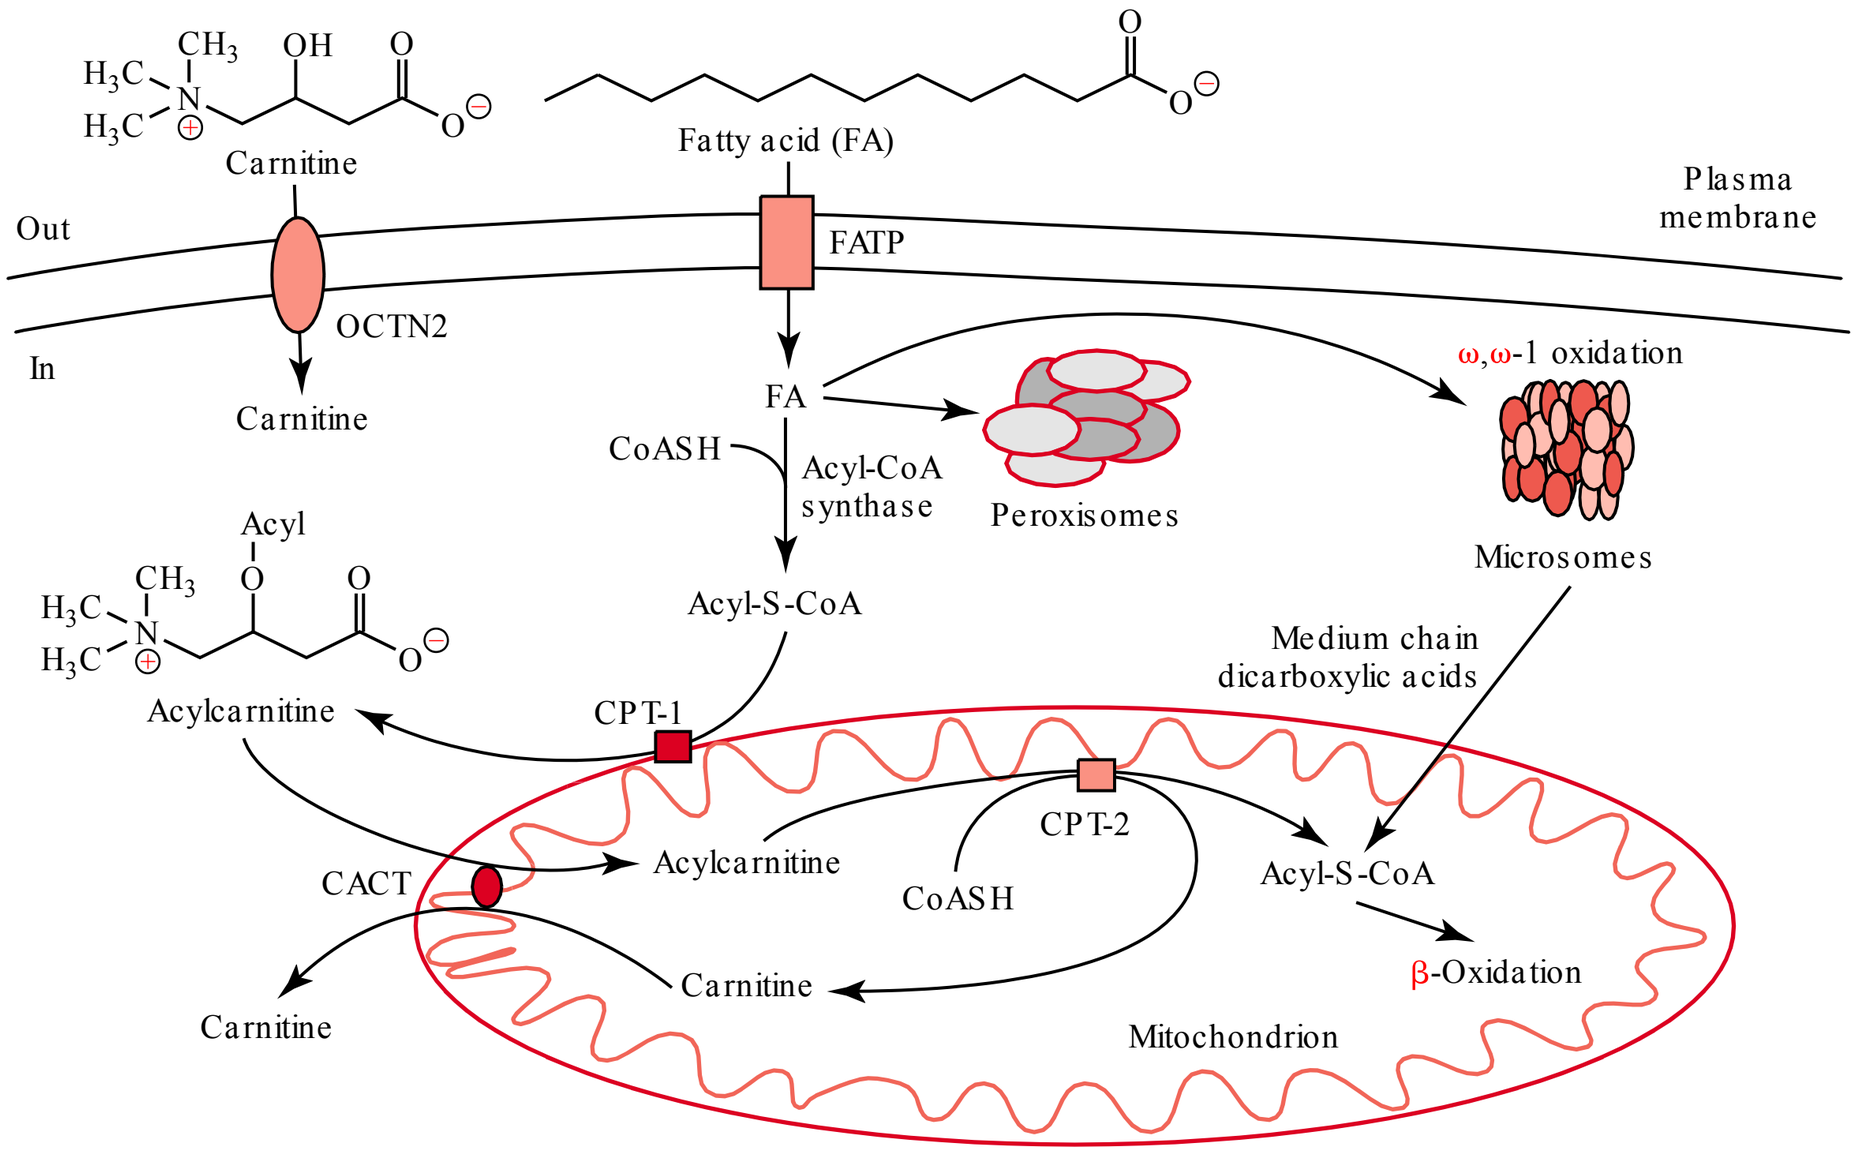

Figure 45-9 The carnitine cycle in fatty acid oxidation. The carnitine cycle is responsible for delivering long-chain fatty acid to the mitochondrial matrix for subsequent beta oxidation. CACT, Carnitine acyl carnitine translocase; CPT-1, carnitine palmitoyl transferase 1; CPT-2, carnitine palmitoyl transferase 2; FA, fatty acid; FATP, fatty acid transporter protein. (Modifed from Longo N, Amat di San Filippo C, Pasquali M. Disorders of carnitine transport and the carnitine cycle. Am J Med Genet C Semin Med Genet 2006;142:77-85.)

intravenous calories in the child who is unable to eat for any reason such as (1) infections, (2) fever, and (3) gastroenteritis. Early diagnosis and therapy reduce the risk of acute dystonia in patients with GAI.[13]

Treatment of Organic Acidemias and Aminoacidopathies

As with the treatment regimens for acidemias, therapy for organic acid disorders consists of (1) special diets restricting the compounds (usually amino acids) that result in the formation of the abnormal organic acid or the accumulation of high concentrations of amino acids, (2) supplementation with vitamins specific for each disorder, (3) carnitine supplements, and (4) sometimes avoidance of fasting. For some of these conditions, aggressive therapy of illnesses with intravenous fuids containing glucose is essential to avoid catabolism that aggravates clinical symptoms.

Disorders of Fatty Acid Oxidation

Fatty acids are metabolized within mitochondria to produce energy. Carnitine and the carnitine cycle are required to transfer long-chain fatty acids into mitochondria for subsequent beta-oxidation (Figure 45-9).[7] There, long-chain fatty acids are progressively shortened of two carbon units at each cycle to generate acetyl CoA, which is used by the Krebs cycle to produce energy (Figure 45-10). **Disorders of fatty acid oxidation**, such as **medium-chain acyl-CoA dehydrogenase (MCAD) deficiency**, occur when an enzyme is missing in the metabolic pathway and fatty acids fail to undergo oxidation to supply energy. These disorders are usually silent and become evident only when the body needs energy from fat during times of (1) fasting, (2) infections, or (3) fever. In this case, apparently healthy children with these disorders (1) become acutely sick, (2) lose consciousness, (3) become comatose, and (4) may die. When symptomatic, patients with fatty acid oxidation disorders develop hypoglycemia and might show increased serum transaminases indicating liver damage. Some fatty acid oxidation disorders (such as **long-chain 3-hydroxyacyl-CoA dehydrogenase [LCHAD] deficiency**) also (1) affect skeletal muscle, (2) affect cardiac muscle, and (3) affect the mother during pregnancy. Other disorders include carnitine transporter defect and very long-chain acyl-CoA dehydrogenase deficiency (see Table 45-1).

Medium-Chain Acyl-CoA Dehydrogenase Deficiency

MCAD (OMIM #201450) deficiency is the most common disorder of fatty acid oxidation with a frequency of 1:6000 to 1:10,000 births among Caucasians.[9] The symptoms of the disease are (1) asymptomatic, (2) hypoglycemia, (3) lethargy, (4) coma, and (5) sudden death, which is usually triggered by prolonged fasting, acute illness, or both. The majority of patients have symptoms in the first year of life, but clinical symptoms can occur at any time during life, and often the

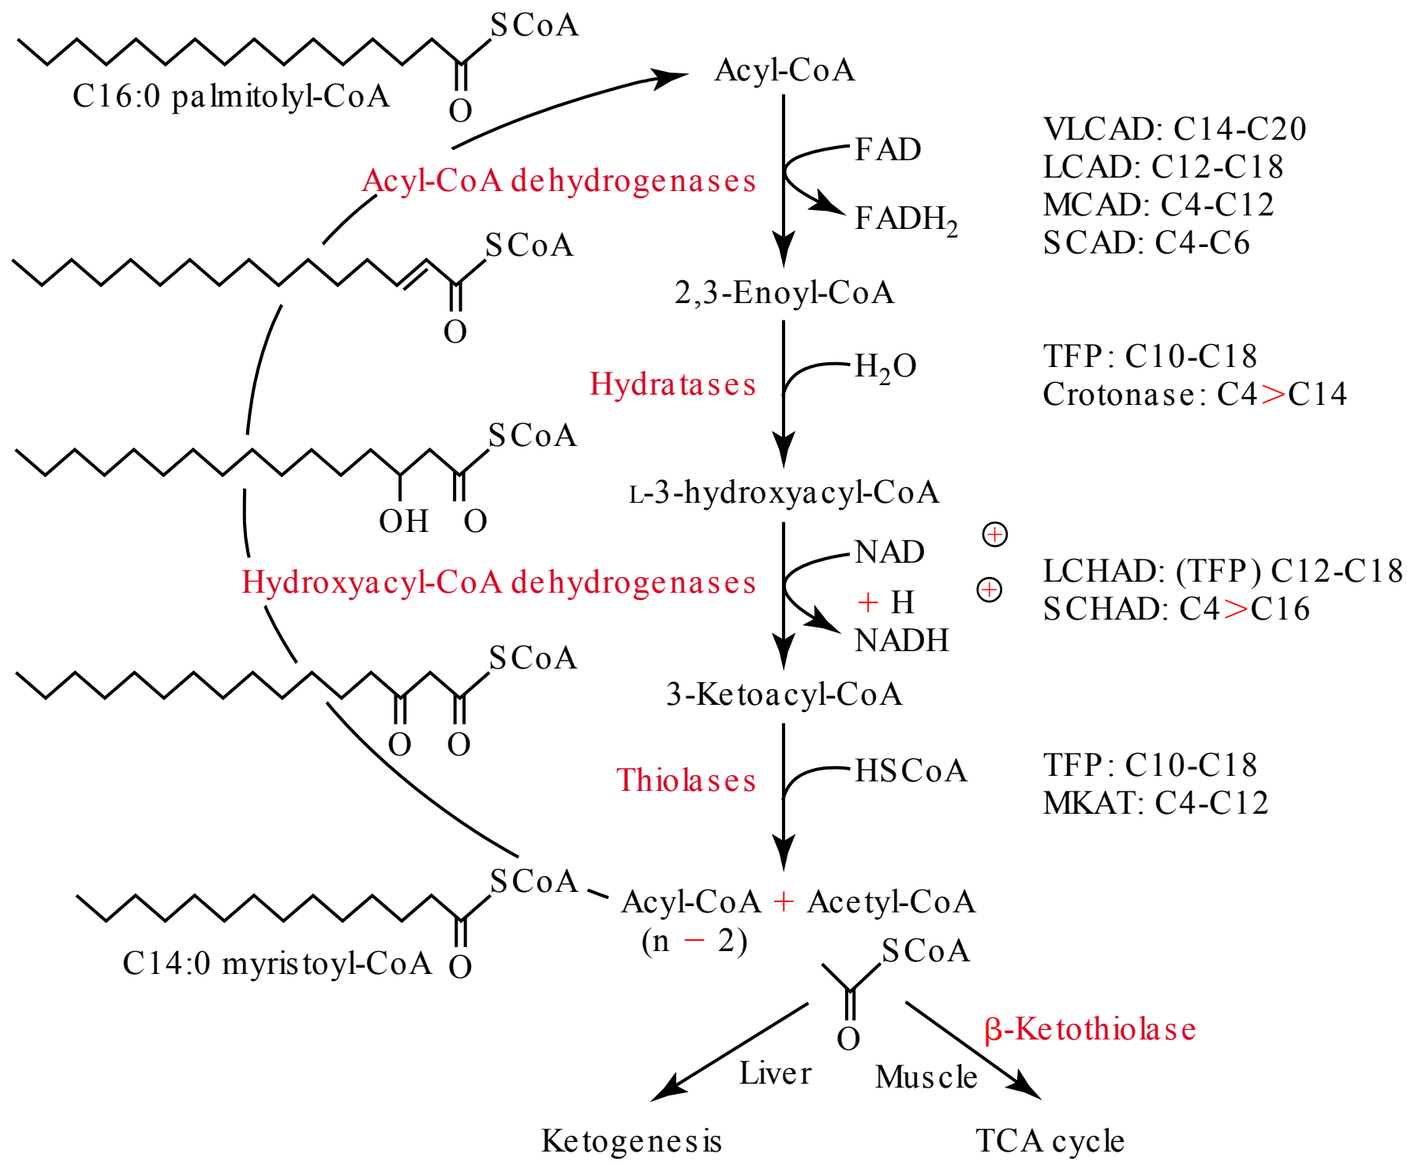

Figure 45-10 Beta oxidation of fatty acids. In the mitochondrial matrix, long-chain fatty acids undergo a series of steps to progressively shorten the fatty acids of two carbon units (acetyl-CoA) through a series of enzymatic reactions. Dehydrogenases that are specifc for fatty acids with different carbon chain lengths (LCAD, long-chain acyl-CoA dehydrogenase; MCAD, medium-chain acyl-CoA dehydrogenase; SCAD, short-chain acyl-CoA dehydrogenase; VLCAD, very long-chain acyl-CoA dehydrogenase) introduce a double bond between C2 and C3. A trifunctional protein (TFP) adds water and cleaves two carbon atoms from the long-chain fatty acid. This is done through sequential action of a hydratase (enoyl-CoA hydratase), a L-3-hydroxyacyl-CoA dehydrogenase (LCHAD, long-chain 3-hydroxyacyl-CoA dehydrogenase), and a thiolase (acyl-CoA acetyltransferase). The two carbon units generated can be completely oxidized in the muscle to CO2 or can generate ketone bodies in the liver that may be exported to other organs to provide energy.

first episode is fatal. T e treatment consists of (1) avoidance of fasting, (2) consumption of low-fat foods, (3) carnitine supplementation, and (4) institution of an emergency plan in case of illness or other metabolic stress. Early diagnosis through newborn screening and early initiation of treatment leads to a favourable prognosis.[14] Patients with MCAD deficiency are identified by MS/MS newborn screening because of the characteristic acylcarnitine profile with increased concentrations of (1) C6- (hexanoyl), (2) C8- (octanoyl), and (3) C10:1- (decenoyl) carnitine and increased C8/C2 and C8/C10 ratios.

T e diagnosis of MCAD is confirmed biochemically by urine organic acid and acylglycine analysis showing (1) excess hexanoylglycine, (2) plasma acylcarnitine profile (confirming increased C6-, C8-, and C10:1 carnitine), and by (3) DNA analysis.[9] Two common mutations have been identified in the ACADM gene of patients with MCAD deficiency. T e most common mutation is a single-nucleotide A-to-G change in exon 11 (c.985A>G) that results in a lysine-for-glutamate amino acid change in the protein (p.K304E). T is mutation is prevalent in symptomatic patients (80% of symptomatic patients are homozygous for this mutation, 98% carry at least one copy) A second mutation, which changes a tyrosine to a histidine (p.Y42H), has been found in asymptomatic newborns identified through MS/MS newborn screening.

Treatment of Fatty Acid Oxidation Disorders

Treatment of fatty acid oxidation disorders consists of (1) avoidance of fasting, (2) adherence to a low-fat diet, and (3) carnitine supplementation. For some disorders of fatty acid oxidation, a diet is indicated that is supplemented with medium chain triglycerides (oil) that enter mitochondria independently from carnitine and bypass the metabolic block. In addition, conditions that increase catabolism such as (1) fever, (2) vomiting, and (3) infections need to be aggressively treated with antibiotics (if necessary) and antipyretics and with intravenous glucose.

Disorders of Carbohydrate Metabolism

Enzyme deficiency in the metabolic pathways for carbohydrates results in accumulation of sugars within organs or

tissues impairing their function, inability to obtain energy from them, or toxicity from the excess of monosaccharides or their derivatives (phosphorylated sugars). **Disorders of carbohydrate metabolism** include the (1) **glycogen storage diseases**, (2) **glucose-6-phosphate dehydrogenase (G-6-PD) deficiency**, and (3) classic galactosemia.

Glycogen storage disorders affect primarily the liver or the skeletal muscle. The accumulation of glycogen impairs organ function and, if the liver is affected, prevents release of glucose with resulting hypoglycemia. They are usually treated with avoidance of fasting and a special diet devoid of simple sugars and supplements with uncooked cornstarch. Glucose-6-phosphate dehydrogenase deficiency affects red blood cells, causing them to break down (hemolysis). It can cause mild to severe jaundice in newborns and in some cases hemolytic anemia. Symptoms can be triggered by (1) infections, (2) certain drugs (some antibiotics and medications used to treat malaria), or (3) exposure to fava beans (a reaction called favism). The gene for this condition is on the X chromosomes and the condition affects mostly males. Avoidance of stressors can mitigate or avoid symptoms.

Classic galactosemia results from absence of galactose-1-phosphate uridyl transferase.[4] Galactose is derived from the disaccharide lactose found in milk. In galactosemia, galactose is phosphorylated to galactose-1-phosphate, but it is not further metabolized. Increased concentrations of galactose-1-phosphate in cells are toxic. Infants have (1) failure to thrive, (2) jaundice, (3) liver failure, and (4) predisposition to sometimes life-threatening infections with E. coli and other Gram-negative bacteria. The treatment of galactosemia involves removal of lactose (contained in human or animal-derived milk, but not in soy milk) and avoidance of all foods containing galactose. In galactosemia, intervention early in life provides the best prognosis although some long-lasting effects may continue to be observed, particularly in girls who for unknown reasons develop ovarian failure. Learning disorders are occasionally observed in treated individuals as well.

Diagnostic Tests for Inherited Disorders of Metabolism

A newborn screening result highly suggestive of a metabolic disorder typically leads to an immediate evaluation using confirmatory tests and a referral of the newborn to a metabolic center.

Types of Confirmatory Tests

In asymptomatic patients, the confirmation of diagnosis relies on specific tests, such as (1) ion-exchange chromatography, (2) liquid chromatography-tandem mass spectrometry (LC-MS/MS) for amino acids analysis, (3) gas chromatography-mass spectrometry (GC-MS) for organic acids analysis, and (4) MS/MS with or without liquid chromatographic separation for acylcarnitines and acylglycines analyses. The combination of these tests is the key in the confirmation of abnormal newborn screening results, especially for those with borderline values. DNA testing and enzyme assays are available for further confirmation of most of these conditions.

These techniques are described in Chapters 12, 13, and 18. Tandem mass spectrometry (MSMS) is a technique of choice in newborn screening programs.

Tandem Mass Spectrometry

The introduction of tandem mass spectrometry (MSMS) as a routine laboratory technique has dramatically increased the number of disorders amenable to newborn screening since multiple metabolites are detected simultaneously in the same blood spot (**multiplex analysis**). This is, allows the identification of several disorders at once, whereas traditional screening techniques were based on one test for one disorder.[2]

Application

In 2005, the American College of Medical Genetics and Genomics (ACMG) released a report, commissioned by the Maternal and Child Health Bureau (MCHB) of the Health Resources and Services Administration (HRSA) with recommendations for a uniform panel for newborn screening (www.acmg.net/; accessed December 17, 2013)[1] This is panel is periodically updated by the Secretary's Advisory Committee on Heritable Disorders in Newborns and Children (www.hrsa.gov/; accessed December 17, 2013). Current recommendations for the uniform screening panel of core conditions include at least (1) five fatty acid oxidation disorders, (2) nine organic acidemias, (3) six aminoacidopathies, (4) two endocrinopathies, (5) three hemoglobinopathies/thalassemias, and (6) six other disorders (see Table 45-1) two of which (hearing loss and critical congenital heart disease) are tested directly in the birth facility. In addition, many secondary conditions have been identified using MS/MS and are routinely reported by most newborn screening programs (Table 45-2).

Methodological Details

MS/MS measures the ratio of the mass (m) of a chemical to its charge z (see Chapter 13 for details of technique). For newborn screening, a tandem mass spectrometer is configured to measure only acylcarnitines and amino acids using the information about their mass and fragmentation pattern. Labelled internal standards are added to the extraction mixtures to quantify the different species.

Interpretation

With MS/MS screening, several analytes are detected at the same time and the interpretation of the results is based heavily on pattern recognition, whereas the measurement of the concentration of the different metabolites supports the interpretation.[3] The ability to detect multiple metabolites by MS/MS allows the use of ratios of metabolites to define whether an increased value is due to a metabolic derangement or to the clinical and nutritional status of the newborn.

Assessment of congenital disorders at the appropriate time after birth is crucial. For example, although amino acid concentrations do not change significantly with newborn

TABLE 45-2 Uniform Screening Panel: Secondary Conditions as Recommended by the Discretionary Advisory Committee on Heritable Disorders in Newborns and Children*

		Metabolic Disorder				
ACMG* Code	Secondary Condition	Organic Acid Condition	Fatty Acid Oxidation Disorders	Amino Acid Disorders	Hemoglobin Disorder	Other Disorder
Cbl C,D	Methylmalonic acidemia with homocystinuria	X				
MAL	Malonic acidemia	X				
IBG	Isobutyrylglycinuria	X				
2MBG	2-Methylbutyrylglycinuria	X				
3MGA	3-Methylglutaconic aciduria	X				
2M3HBA	2-Methyl-3-hydroxybutyric aciduria	X				
SCAD	Short-chain acyl-CoA dehydrogenase deficiency		X			
M/SCHAD	Medium/short-chain L-3-hydroxyacl-CoA dehydrogenase deficiency		X			
GA2	Glutaric acidemia type II		X			
MCAT	Medium-chain ketoacyl-CoA thiolase deficiency		X			
DE RED	2,4 Dienoyl-CoA reductase deficiency		X			
CPT IA	Carnitine palmitoyltransferase type I deficiency	X				
CPT II	Carnitine palmitoyltransferase type II deficiency	X				
CACT	Carnitine acylcarnitine translocase deficiency	X				
ARG	Argininemia			X		
CIT II	Citrullinemia type II			X		
MET	Hypermethioninemia			X		
H-PHE	Benign hyperphenylalaninemia			X		
BIOPT (BS)	Biopterin defect in cofactor biosynthesis			X		
BIOPT (REG)	Biopterin defect in cofactor regeneration			X		
TYR-II	Tyrosinemia type II			X		
TYR-III	Tyrosinemia type III			X		
Var Hb	Various other hemoglobinopathies				X	
GALE	Galactoepimerase deficiency					X
GALK	Galactokinase deficiency					X
	T-cell related lymphocyte deficiencies					X

*Note: These disorders are detected in the differential diagnosis of core disorders listed in Table 45-1. The nomenclature for conditions is based on data from reference 12.[12]
ACMG, American College of Medical Genetics and Genomics.
Adopted from American College of Medical Genetics and Genomics. newborn screening: towards a uniform screening panel and system. Genetic Med 2006;8(5) Suppl:S12-S252.

age, acylcarnitine concentrations vary significantly. For most acylcarnitines, the concentrations are highest in the first week of life and decrease rapidly afterwards. In some states, a second screening test is mandated at 1 to 4 weeks of age. Age-appropriate cutoff values for all screening tests should be used for the interpretation of newborn screening results.

Review Questions

1. An inherited disorder that affects the conversion of nutrients into energy is referred to as a(n)
   a. aminoacidopathy.
   b. autosomal recessive disorder.
   c. inborn error of metabolism (IEM).
   d. hemolytic disease of a newborn.
2. Tandem mass spectrometry (MS/MS) involves
   a. an ultraviolet laser to ionize small amounts of matrix and analyte that are directed into the mass analyzer.
   b. screening a large number of infants for disorders of amino acid metabolism using different growth antagonists.
   c. an ion trap designed to trap ions in three dimensions instead of two dimensions.
   d. assessment of the mass-to-charge ratio of a chemical.
3. An inborn disorder of metabolism that is triggered by prolonged fasting and/or acute illness and that is confirmed by abnormal acylcarnitine concentrations is
   a. galactosemia.
   b. medium-chain acyl-CoA dehydrogenase (MCAD) deficiency.
   c. phenylketonuria (PKU).
   d. glutaric acidemia type I (GAI).

4. Deficiency of an enzyme that results in excess of monosaccharides in the blood of a newborn leads to a specific disorder of metabolism. An example of this type of disorder would be
   a. galactosemia.
   b. medium-chain acyl-CoA dehydrogenase (MCAD) deficiency.
   c. phenylketonuria (PKU).
   d. glutaric acidemia type I (GAI).
5. The disorder that is identified by increased serum glutarylcarnitine and urine glutaric acid (GA) on newborn screening is characterized by dysfunctional metabolism of
   a. hydroxylysine and phenylalanine.
   b. tyrosine and tryptophan.
   c. tryptophan, hydroxylysine, and lysine.
   d. cystine and hydroxylysine.
6. In a disorder that has an autosomal recessive inheritance pattern, what is the risk of two carrier parents having an affected child with that disorder?
   a. 0%
   b. 25%
   c. 50%
   d. 100%
7. In relation to newborn screening for inborn errors of metabolism (IEMs), second-tier testing is done to
   a. assess the parents of the newborn for possible carrier status.
   b. assess the siblings of the newborn for similar symptoms or disorders.
   c. determine the number of false negatives that might have occurred with initial screening.
   d. further assess a positive screening test result by targeting more specific analytes.
8. The disorder of amino acid metabolism in which the parent amino acid accumulates in blood and spills over into urine is classified as
   a. an organic acidemia.
   b. an aminoacidopathy.
   c. a carbohydrate disorder.
   d. a disorder of fatty acid oxidation.
9. The simultaneous analysis of multiple analytes using a single sample, such as a blood spot from a newborn, is referred to as
   a. multiplex analysis.
   b. newborn screening.
   c. tandem mass spectrometry (MS/MS).
   d. multiple of means.
10. The enzyme that is absent in the aminoacidopathy phenylketonuria (PKU) is
    a. phenylalanine decarboxylase.
    b. ornithine translocase.
    c. phenylalanine hydroxylase.
    d. succinyl-coenzyme A (CoA) mutase.

CHAPTER 46

Pharmacogenetics

Gwendolyn A. McMillin, Ph.D., D.A.B.C.C. (C.C., T.C.)

Objectives

1. Define the following:
   - Adverse drug reaction (ADR)
   - Cytochrome P450 (CYP)
   - Haplotype
   - Metabolizer
   - Pharmacodynamics
   - Pharmacogenetics
   - Pharmacokinetics
   - Phase I/II enzyme
   - Prodrug
   - Single-nucleotide polymorphism
2. List and describe three characteristics of a drug-gene pair that contribute to successful clinical implementation of a pharmacogenetic test.
3. Compare genotyping and phenotyping in regard to pharmacogenetic testing, including how each is determined, limitations in testing, and the continued need for therapeutic drug monitoring.
4. List the general actions that Phase I and Phase II enzymes have on substrates.
5. For each of the following enzymes, state whether it is a Phase I or Phase II enzyme, list the specific substrates of each enzyme, and state whether the substrate is a prodrug and the action of the enzyme on that substrate:
   - Cytochrome P450 2C19 (CYP2C19)
   - Cytochrome P450 2C9 (CYP2C9)
   - Cytochrome P450 2D6 (CYP2D6)
   - Dihydropyrimidine dehydrogenase (DPD)
   - N-acetyltransferase 1 (NAT1)
   - N-acetyltransferase 2 (NAT2)
   - Thiopurine S-methyltransferase (TPMT)
   - UDP-Glucuronosyltransferase 1A1 (UGT1A1)
   - Vitamin K epoxide reductase (VKOR)
6. For the HLA-B gene and the HLA-B*5701 allele, describe the relationship of allelic variants with drug hypersensitivity, including associated phenotypes and laboratory analysis.
7. Analyze and resolve case studies related to pharmacogenetic testing in the laboratory.

Key Words and Definitions

Acute lymphoblastic leukemia (ALL) An acute, rapidly progressing form of leukemia that is characterized by the presence in the blood and bone marrow of large numbers of unusually immature white blood cells destined to become lymphocytes.

Adverse drug reaction (ADR) Any undesirable side effect or toxic reaction that is caused by the administration of a drug.

Allele One of the alternative versions of a gene at a given location (locus) along a chromosome. An individual inherits two alleles for each gene, one from each parent. If the two alleles are the same, the individual is homozygous for that gene. If the alleles are different, the individual is heterozygous. The term now also refers to variation among non-coding DNA sequences in addition to genes.

Cytochrome P450 (CYP) A large family of metabolic enzymes that catalyze the oxidations of organic substrates. They are important in metabolism of drugs, steroid hormones, fatty acids, and other substances.

Drug metabolism The process by which drugs are chemically modified in the body.

Gene duplication A process by which a chromosome or a portion of DNA is duplicated, resulting in an additional copy of a gene. Also referred to as chromosomal duplication or gene amplification.

Genotype The genetic makeup of an individual or a group of individuals. An individual's genotype codes for that individual's phenotype. The genotype for a specific gene requires knowledge of both alleles of the gene.

Genotyping Laboratory testing designed to detect specific genetic variants that are used to identify and classify variant alleles. The alleles are reported together as a genotype that may or may not be predictive of a phenotype.

Gilbert syndrome A common hereditary cause of increased bilirubin; found in up to 5% to 10% of the population.

Haplotype A combination of alleles (for different genes) that are located closely together on the same chromosome and that tend to be inherited together.

Key Words and Definitions—cont'd

International normalized ratio (INR) A method of reporting prothrombin time results for patients receiving oral anticoagulant therapy

Irinotecan A DNA topoisomerase inhibitor used as an antineoplastic drug in the treatment of colorectal carcinoma.

Metabolizer classification A classification of four drug-metabolism phenotypes as they relate to an individual's metabolic efficiency for processing a specific therapeutic drug. The four types are (1) poor metabolizers (PMs), (2) ultra-rapid metabolizers (UMs), (3) extensive metabolizesr (EMs), and (4) intermediate metabolizers (IMs).

N-acetyltransferase (NAT) A family of metabolic enzymes that acetylate drugs.

National Institutes of Health (NIH) Pharmacogenomics Research Network (PGRN) A network of scientists focused on understanding how a person's genes affect his or her response to medicines.

Pharmaceutical drug Any chemical substance intended for use in the (1) medical diagnosis, (2) cure, (3) treatment, or (4) prevention of disease. Also referred to as a medicine or medication.

Pharmacodynamics A process that defines how a drug acts on its target and its mechanisms of action.

Pharmacogenetics Study of the variations in single genes or small groups of related genes that affect the response to a drug, including its metabolism.

Pharmacogenomics The study of how combinations of variations in several genes, potentially extended to the complete genome, influence the pharmacology of a drug(s).

Pharmacogenomics Knowledge Base (PharmGKB) An integrated resource about how variation in human genetics leads to variation in response to drugs; database of information about genes (pharmacogenes) involved in modulating the response to drugs.

Pharmacokinetics A process describing how a drug is (1) absorbed, (2) distributed, (3) metabolized, and (4) eliminated.

Phenocopying The alteration of a phenotype through a non-genetic, environmental mechanism.

Phenotype The observable physical or biochemical characteristics of an individual, as determined by their genetic makeup and environmental influences.

Phenotyping Laboratory testing designed to measure or predict the reaction or response of an individual to a stimulus (such as, a specific drug). A drug-related phenotype is based upon an individual's genes, but it is also influenced by non-genetic factors, such as concomitant medications, liver function, and renal function.

Prodrug A drug that is administered in an inactive or poorly-active form and is converted to an active drug by metabolism.

Pseudogene A defective segment of DNA that resembles a gene but cannot be transcribed.

Severe cutaneous adverse reaction syndromes (SCARS) A group of serious skin conditions that are characterized by blisters and epidermal detachment.

Single-nucleotide polymorphism (SNP) (Pronounced "snips.") A DNA sequence variation that occurs at appreciable frequency in the population.

Star (*)-allele nomenclature An nomenclature developed to standardize genetic polymorphism annotation for the cytochrome P450 genes.

Stevens-Johnson syndrome (SJS) A serious allergic reaction with a characteristic rash involving the skin and mucous membranes. The hypersensitive (allergic) reaction may be initiated by drugs, infectious agents, or other stimuli.

Thiopurine S-methyltransferase (TPMT) A metabolic enzyme that methylates and thereby inactivates certain antimetabolites, such as 6-mercaptopurine (6-MP) (cancer therapeutic).

Toxic epidermal necrolysis (TEN) A rare condition that causes large portions of the epidermis (the skin's outermost layer) to detach from the layers of skin below.

Uridine 5′-diphosphate (UDP)-glucuronosyltransferase (UGT) A family of metabolic enzymes that conjugate compounds with glucuronide molecules.

Pharmacogenetics is a term originating from merging the expressions pharmacology (the study of drugs) and genetics (the study of inherited traits). Pharmacogenetic testing is a term describing a process that predicts or explains how an individual (based on their **genotype**) will respond to (1) **pharmaceutical drugs**, (2) medicines, and (3) other pharmacologically or toxicologically active compounds. Related work associating drug handling and response with the entire genome is known as **pharmacogenomics**, although some use that term and pharmacogenetics interchangeably.

Genotype and phenotype are terms of particular relevance to the understanding of the discipline of pharmacogenomics. Biologically, the genotype of an individual is the inherited set of instructions one carries within his or her genetic code. This code is expressed through one's **phenotype** (the composite of one's observable characteristics or traits). Relating these definitions to the practice of administering pharmaceutical drugs, pharmacogenomics is based on the premise that one's genotype carries the code for how one metabolizes and utilizes a particular drug or group of drugs, and subsequently one's phenotype is a reflection of how this genetic code is executed. Therefore, if basic studies have provided the necessary genotypic and phenotypic data for a particular drug's metabolism and utilization, then pharmacogenetic testing of an individual will provide the information that then would be used to predict their phenotype and ultimately guide drug and dose selection for that individual.[10] For example, predicted phenotype information would be medically useful for (1) selecting or avoiding a specific drug(s), (2) selecting the optimal dose, (3) selecting the optimal dosing interval for a given patient, (4) avoiding and minimizing the incidence of **adverse drug reactions (ADR)**, and (5) avoiding and minimizing drug hypersensitivity.

Approximately 10% of all drug labels now include references to pharmacogenetic findings, and several pharmacogenetic

tests are available clinically that are designed to identify patients that may be genetically predisposed to ADRs or therapeutic failure.[3] However, incorporation of pharmacogenetics into routine prescribing decisions for most drugs requires further development and validation of specific dosing guidelines and algorithms.

This chapter presents a general introduction to pharmacogenomics and human pharmacogenetic testing and several polymorphic genes and specific applications to drug selection/avoidance decisions are discussed.

Defining Pharmacogenetic Targets

Response to drugs, whether desirable (therapeutic) or undesirable (toxic), depends on many variables, such as (1) drug formulation, (2) route of administration, (3) clinical status, (4) age, (5) sex, (6) co-medications, and (7) genetics. However, most drugs are historically dosed according to population-derived recommendations. Dosing is typically optimized through trial and error, based on how a patient handles and responds to a drug. Minimizing this process of trial and error is one of several tactics proposed to reduce the incidence of ADRs and improve rates of response.[10] Specifically, pharmacogenetic testing is used to understand and predict some aspects of **pharmacokinetics** and **pharmacodynamics**. These processes are described briefly in the next two paragraphs; see Chapter 30 of this textbook for further discussion and detail.

Pharmacokinetics describes how the body acts on a drug, including (1) absorption, (2) distribution, (3) metabolism, and (4) elimination. Pharmacokinetic targets may therefore represent genes that code for (1) transport proteins, (2) metabolic enzymes, and (3) drug-binding proteins. Pharmacokinetics is often evaluated by measuring drugs and their metabolites in biological fluids that are collected at specific times relative to the time of drug administration. From these results, time-versus-concentration curves are generated, and parameters (such as, clearance) are calculated. Metabolic ratios (such as, metabolite concentration divided by parent drug concentration) are also used to evaluate variation in pharmacokinetics.

Pharmacodynamics describes how a drug elicits responses and whether the response is desirable or undesirable. Pharmacodynamic targets may represent genes that code for (1) enzymes, (2) receptors, (3) ion channels, and (4) other signaling proteins. Response to a drug may or may not show a relationship to drug dose or to the concentration of drug in blood. Pharmacodynamics are measured for some drugs with biomarkers or clinical measurements.

The first recognized pharmacogenetic targets described variation in **drug metabolism** (pharmacokinetics). The early focus on drug metabolism reflects the fact that measurements of drug and drug metabolite concentrations in biological fluids define a phenotype, and that biological fluids (usually blood or urine) are reasonably accessible for testing. Several metabolic phenotypes were (1) characterized, (2) found to cluster within families, and (3) later explained by specific gene variants.

Metabolic phenotypes reflect either poor or rapid drug metabolism. Metabolism of a drug either inactivates or activates the drug. Each metabolite exhibits unique pharmacokinetic and pharmacodynamic phenotypes as well and may undergo subsequent metabolic reactions. As such, there may be several important metabolites to consider for a single drug; each metabolite may be more or less active than the parent drug, and it may be eliminated more rapidly or more slowly than the parent drug.

Currently, most drug-gene associations are not sufficiently studied to be used routinely for directing clinical therapy. And, it is (1) not practical, (2) medically indicated, nor (3) cost-effective to provide pharmacogenetic profiles for every protein known to be associated with every drug. Based on successful applications to date, pharmacogenetic targets are most likely to be successful clinically when they:

1. Define a major pathway for metabolism of, or response to, a specific drug, thereby providing clear guidance for drug selection or avoidance.
2. Are associated with a clinically significant and actionable effect on the relationship between dose and plasma drug concentration or a measurable biomarker.
3. Predict dosing for a drug that is known to be clinically challenging, such as due to (1) a narrow therapeutic index, (2) limited temporal opportunity to exert efficacy, or (3) a requirement for a long period of taking the drug to determine if the drug is effective in that patient.

The utility of pharmacogenetic testing may be compromised when (1) alternative drugs are not available, (2) incorporation of pharmacogenetic testing does not clearly improve patient care, (3) less sophisticated or less expensive tools or tests are sufficient for making prescribing decisions, or (4) accommodations to specific dose or dosing strategies are not available. Some specific gene-drug relationships for which the drug labeling includes pharmacogenetic information are shown in Table 46-1. Although these gene-drug examples apply to specific areas of medicine, other areas of medicine are likely to benefit from pharmacogenetic testing as well.

Approaches to Pharmacogenetic Testing

In practice, pharmacogenetic testing is a tool that a clinician uses to predict that a patient is likely to (1) fail therapy, (2) suffer an ADR, or (3) exhibit altered pharmacokinetics. This knowledge then assists the clinician in (1) selection/avoidance of a drug, (2) establishing a drug dosage, and (3) establishing a dosing frequency with intent to improve success of therapy.

Pharmacogenetic testing may be accomplished through phenotype or genotype testing. Table 46-2 compares characteristics of the phenotype and the genotype. **Phenotyping** can be done before or after administration of a drug. Phenotyping before administration of a drug can be accomplished by various techniques, such as measurement of metabolic ratios in blood or urine after administration of a probe drug, or use of functional tests that reflect key enzymes or proteins involved in drug metabolism or response. Such testing is not common today. Post-therapeutic phenotyping, however, particularly therapeutic drug monitoring, is used to personalize

TABLE 46-1 Examples of Germline Pharmacogenetic Relationships in Medicine Today

Drug	Relevant Area of Medicine	Approximate Rate of ADRs or Resistance	Gene or Allele	Other Drugs with Pharmacogenetic Relationship
6-Mercaptopurine	Oncology	Up to 10% ADRs	TPMT	Azathioprine, 6-thioguanine
Irinotecan	Oncology	Up to 40% ADRs	UGT1A1	Topotecan, nilotinib, protease inhibitors
5-Fluorouracil	Oncology	20% ADRs	DYPD	Capecitabine
Tamoxifen	Oncology	30% resistant	CYP2D6	Risperidone, fluoxetine, codeine, atomoxetine, amiodarone, doxorubicin
Nortriptyline	Psychiatry	Up to 10% ADRs		
Abacavir	Infectious disease	Up to 10% ADRs	HLA-B*5701	
Warfarin	Cardiology	Up to 40% ADRs	CYP2C9, VKORC1	
Clopidogrel	Cardiology	30% resistant	CYP2C19	Voriconazole, omeprazole, diazepam, antidepressants

ADRs, Adverse drug reactions.

TABLE 46-2 Comparing Phenotype and Genotype Testing Strategies

	Phenotype	Genotype
Represents	"State" represents current response; may not represent inheritance	"Trait" represents inheritance; may not be consistent with the phenotype
Sensitive to gene expression	Yes	No
Sensitive to protein function	Yes	No
Requires collection of multiple specimens	Commonly	No
Requires administration of a probe drug	Possibly	No
Other limitations	• Timing of specimen collection may be critical • May not be appropriate for patients who recently received a blood transfusion • May be influenced by co-medications (drug-drug interactions)	• May not detect all clinically relevant genes and/or alleles • Genotype-phenotype relationship (interpretation) may not be known

drug therapy and should help to adjust for pharmacogenetic or other sources of variation in drug handling and/or drug response.

The value of **genotyping** depends on a strong genotype-phenotype correlation. In the simplest scenario, a genotype result accounts for 100% of the anticipated phenotype. Unfortunately, completely definitive genotype-phenotype relationships (100% certainty) are rare—a fact that creates controversy surrounding the value of a single-gene association. Limitations in testing and the possibility of false-negative results due to the targeted nature of most pharmacogenetic testing may also reduce the clinical utility of genotyping, as will inter-individual variation in gene expression, and non-genetic factors, such as drug-drug or drug-food interactions. As such, genetic testing may guide initial drug and dose selection, but post-therapeutic monitoring that evaluates the patient "state" may be required to verify or further optimize dose of that drug. Indeed, neither phenotyping nor genotyping is intended to replace the need for clinical assessments of drug response.

Clinical Applications of Pharmacogenetic Testing

Pharmacogenetic testing is clinically useful only when information is sufficient to clearly guide drug and/or dose selection. While many examples of this type of information are found in the peer-reviewed literature, most of the available data came from retrospective studies. The **Pharmacogenomics Knowledge Base (PharmGKB)**[4] is a publicly available Internet research tool developed by Stanford University with funding from the **National Institutes of Health (NIH)** and is part of the **NIH Pharmacogenomics Research Network (PGRN)**, a nationwide collaborative research consortium (http://www.nigms.nih.gov/;accessed December 18, 2013). Its aim is to aid researchers in understanding how genetic variation among individuals contributes to differences in reactions to drugs. This is regularly updated database is an excellent source of genetic and clinical information derived from research studies at various medical centers worldwide.[8] Organized registries for clinical studies (such as, http://clinicaltrials.gov; accessed December 18, 2013) are also good resources. It is anticipated that drugs previously removed from development because of ADRs will be reconsidered if genetic tests identify individuals at high risk for ADRs, who could avoid use of that drug. Thus, companion diagnostics and pharmacogenetic-based dosing guidelines are likely to be introduced. Indeed, the US Food and Drug Administration (FDA) has published a draft guidance for companion diagnostics, and several such products are currently cleared and referenced on their website (http://www.fda.gov/;accessed December 18, 2013).

Some of the most successful pharmacogenetics tests in existence today support diverse medical disciplines, including (1) oncology, (2) psychiatry and neurology, (3) cardiology, and (4) infectious disease. Each of these clinical disciplines utilizes medications that exhibit substantial inter-individual variability in response and toxicity profiles. Although pharmacogenetic test results do not guarantee selection of the best drug at the best dose for an individual patient, testing does provide information that is used to guide pharmacotherapy decision-making and help identify whether individual patients are suitable or unsuitable candidates for a particular drug. Pharmacogenetic testing may also help identify patients that may require additional monitoring, relative to generalized population-based recommendations. A number of common drugs and genes that serve as examples of successful pharmacogenetic applications are listed in Table 46-1. These specific genes and how they predict or explain variation in pharmacokinetics and/or pharmacodynamics of certain drugs are discussed later.in the next paragraphs.

Drug Metabolism and Pharmacogenomics

Metabolism of drugs is often described in terms of phase I and phase II reactions. Most phase I reactions are oxidative and are mediated by **cytochrome P450 enzymes (CYPs)**. They are the major enzymes involved in drug metabolism and bioactivation, accounting for about 75% of the total number of different metabolic reactions. Phase II reactions typically involve enzymes that conjugate drug analytes with (1) acetyl, (2) glucuronosyl, (3) amino acyl, or (4) sulfate groups. Despite the name, phase II reactions may occur before or after phase I reactions, or independently.

Phase I Cytochrome P450 Enzymes

CYPs are heme-containing enzymes that are synthesized from a superfamily of CYP genes, classified into families, and further classified into subfamilies, based on amino acid homology.* They were originally termed P450 cytochromes with the "450" referring to the 450-nanometer absorption maximum of a carbon monoxide binding pigment found in the microsomes of liver.

The major CYPs involved in drug metabolism are (1) cytochrome P450 1A2 (CYP1A2), (2) cytochrome P450 2B6 (CYP2B6), (3) cytochrome P450 2C9 (CYP2C9), (4) cytochrome P450 2C19 (CYP2C19), (5) cytochrome P450 2D6 (CYP2D6), (6) cytochrome P450 2E1 (CYP2E1), and the (7) cytochrome P450 3A family, particularly CYP3A4 and CYP3A5.[17] CYP2D6, CYP2C9, and CYP2C19, are discussed in more detail later. Genetic variants of the CYPs are associated with changes in enzyme (1) activity, (2) stability, and (3) substrate affinity that leads to clinically significant phenotypes. In addition to genetic variability, many CYP isoenzymes are susceptible to dramatic differences in expression (more than 1000-fold), based on (1) age, (2) clinical status, and (3) food/drug interactions.

*By convention, names of genes are italicized. For example, CYP2E1 is the gene that encodes the cytochrome CYP2E1.

The relationship of CYPs as drug (1) substrates, (2) inhibitors, and (3) inducers is described in the package labeling for individual drugs and summarized in many books, websites, and other resources. Only selected drug examples, which have thoroughly-described pharmacogenetic targets, will be discussed here, but all the CYP families exhibit genetic variation that could influence optimal prescribing practices for drugs that are substrates for them.

Alleles for all CYP genes are described according to an international consensus classification termed the **Star (*)-allele nomenclature**.[6,15] For example, the "star 1" allele is the normal allele and codes for a protein predicted to function with full enzymatic activity and to be expressed in typical quantities. Often *1 describes a situation where no variant alleles are detected. Therefore, the true accuracy of a *1 allele designation is dependent on whether the assay used to make that call is comprehensive. All alleles are described with a star followed by a number, and possibly a letter to describe an allele subtype. Subtypes have not been shown to influence the clinical phenotype, thus far, but could be important for future **haplotype** assignment or to support research studies. Numerical assignments of other alleles (after *1) are based largely on chronology of identification, wherein alleles identified earliest in time have the lowest numbers.

Common alleles for CYP2D6, CYP2C9, and CYP2C19 are shown in Table 46-3. A **single-nucleotide polymorphism (SNP**/pronounced "snip") that is frequently used to detect each allele is bolded, but in many cases detection of other SNPs is required to accurately classify an allele. The effects of the genetic variation are shown, where known, both in vitro and in vivo. A model for assignment of estimated phenotype predictions from genotype is illustrated for CYP2D6 in Figure 46-1, which in principle, applies to other CYPs as well. As shown in the figure and discussed in more detail later, the genotype predicts phenotype based on the presumed composite of the alleles detected, and it must be considered relative to other factors that could influence the phenotype.

Cytochrome P450 2D6

CYP2D6, originally named debrisoquine hydroxylase, is known to metabolize more than 100 drugs and environmental toxins.[14] It frequently is implicated in ADRs and has been the subject of many US FDA-issued public health advisories. Metabolic phenotypes of CYP2D6 are best described as a continuum that varies from no activity to very high activity. For ease of characterization, CYP2D6 activity is classified according to the **metabolizer classif cation**. This scheme contains four phenotypes: (1) ultra-rapid metabolizers (UMs), (2) extensive (normal) metabolizers (EMs), (3) intermediate metabolizers (IMs), and (4) poor metabolizers (PMs). Translation of a phenotype to a clinical application is somewhat difficult because the actual phenotype is dependent not only on the genetic makeup of CYP2D6, but also on (1) expression of CYP2D6, (2) whether drug-drug interactions affect the phenotype, and (3) whether CYP2D6 activates or inactivates the drug of interest. CYP2D6 is inhibited by several compounds, some of which are also substrates. For example, when a CYP2D6

TABLE 46-3 Common CYP2D6, CYP2C9, and CYP2C19 Alleles*

Allele	Nucleotide Changes (cDNA)	Effect	Enzyme Activity	
			In Vivo	In Vitro
CYP2D6*1A	None		Normal	Normal
CYP2D6* xN	Based on alleles duplicated	N active genes	Increased for functional alleles

Modified from the Human Cytochrome P450 (CYP) Allele Nomenclature Committee. Available at: http://www.CYPalleles.ki.se/; accessed on February 6, 2014. Reproduced with permission of Sarah C. Sim, Webmaster.
No information regarding enzyme activity is listed in the above table when none was present at this reference.

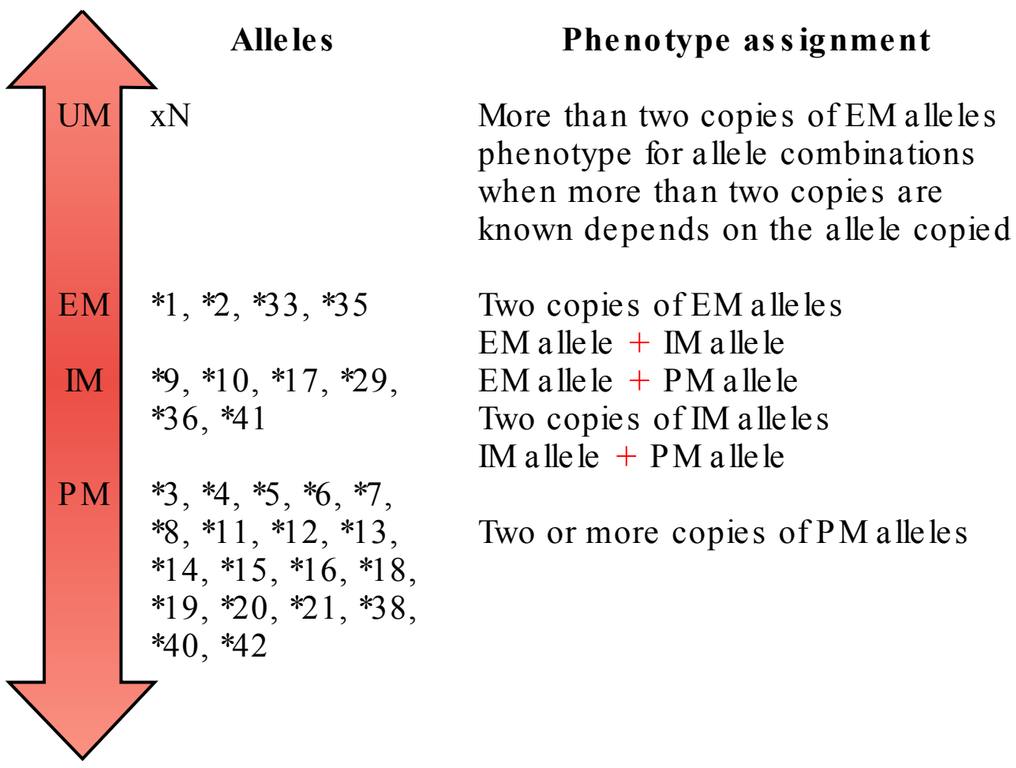

Figure 46-1 CYP2D6 phenotype is estimated based on the combination of alleles detected. Shown here is a continuum of metabolic phenotypes: poor metabolizer (PM), extensive metabolizer (EM, normal), intermediate metabolizer (IM), and ultra-rapid metabolizer (UM). The alleles that correspond to enzyme activity are also listed, adjacent to the formulas for establishing a clinical phenotype, based on the combination of two or more alleles.

inhibitor is administered along with a CYP2D6 substrate, the phenotype for the patient may appear impaired. This process, known as **phenocopying**, is defined as the alteration of a phenotype through a non-genetic, environmental, mechanism. It is of clinical relevance for CYP2D6.

The relationship between function of the CYP2D6 enzyme (phenotype) and the CYP2D6 genotype has been extensively characterized, but it is still not well defined for all genotypes, particularly genotypes that predict the impact of IM phenotype. More than 100 allelic variants have been described in the CYP2D6 gene, including complete gene deletions and duplications. Examples of the most common CYP2D6 alleles, listed with associated nucleotide changes and known effects on enzyme activity of CYP2D6, are shown in Table 46-3. Effects on enzyme activity are used to group the alleles according to the predicted phenotype, assuming that two alleles were inherited. However, the actual phenotype reflects a sum of the alleles and non-genetic factors. Among Caucasians, approximately 2% are genetically UM, and 10% are PM. Only 1% to 3% of Blacks and Asians are PMs, but many are IMs.

The CYP2D6 phenotype that is most simple to characterize is the PM phenotype, for which essentially zero CYP2D6 activity is anticipated. The PM phenotype is expected when two or more copies of PM alleles are inherited (see Figure 46-1). Other phenotype assignments are based on the highest functioning phenotype prediction. For example, at least one functional EM allele is thought to generate a phenotype that falls within the limits of normal. The UM phenotype is assigned when more than two copies of functional EM alleles are identified (xN); this is often referred to as a **gene duplication**. Duplication of PM alleles has no effect on the phenotype, and duplication of IM alleles may or may not affect the phenotype.

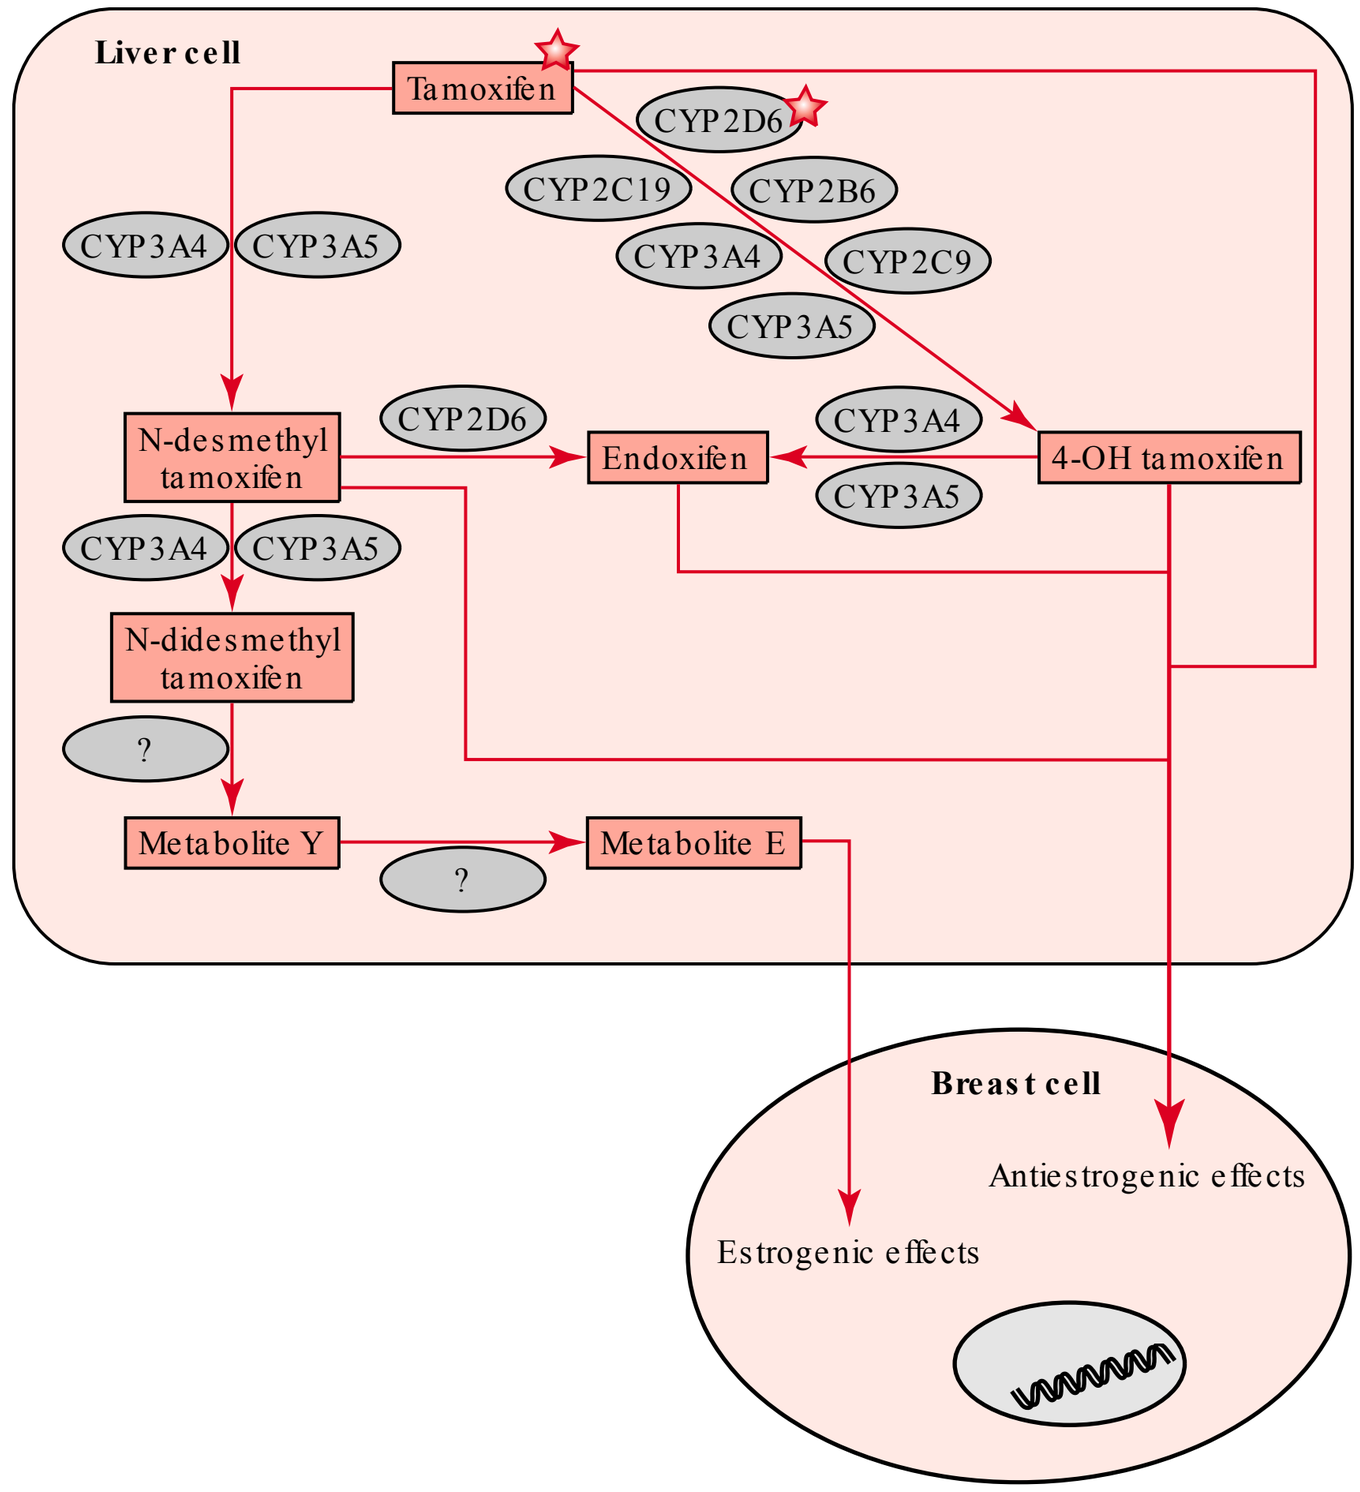

Figure 46-2 Illustrated pharmacokinetic and pharmacodynamic pathways for tamoxifen. Cytochrome P450 (CYP) isozymes are involved in the activation and inactivation of tamoxifen, and cytochrome P450 2D6 (CYP2D6) is key to production of the active metabolite, endoxifen. Most of the antiestrogenic effects of tamoxifen are attributed to endoxifen. Many additional factors in the pharmacokinetics and pharmacodynamics of tamoxifen are not known. (Reproduced by permission from PharmGKB and Stanford University.)

The CYP2D6 gene, like many other CYP genes, is challenging to genotype because of (1) the presence of the **pseudogenes**, (2) the sheer number of genetic variants, (3) the complexity of the genetic variants, and (4) the need for identification of gene dose, specifically, duplications and deletions of the gene. CYP2D6 pharmacogenetic screening protocols vary tremendously in ability to accurately detect gene dose and to detect many versus only a few of the most common variants. It is important that an assay identify a sufficient number of variants to accurately classify an allele. For example, both the CYP2D6*10 and CYP2D6*4 alleles contain the 100C →T variant.* Because the phenotype predictions differ for the two alleles, it is clinically relevant to determine which allele is present. The pattern of additional SNPs unique to each allele helps distinguish the two and suggests the likelihood that both alleles could be present. Examples of how pharmacogenomic testing of CYP2D6 would have clinical utility in guiding the administration of (1) tamoxifen, (2) codeine, and (3) antidepressants are presented later.

Examples of the pharmacogenomics application of CPY2D6 are in the administration of tamoxifen, codeine and nortriptyline.

*A form of nomenclature that indicates a replacement of a cytosine molecule for a thymidine molecule at position 100 in a gene.

Tamoxifen

Tamoxifen is widely used to treat and prevent breast cancer. Tamoxifen mediates its therapeutic effects through modulation of estrogen receptors, leading to suppression of estrogen-mediated cell proliferation. Therefore, hormone-sensitive breast tumors (estrogen receptor–positive) are most likely to respond to tamoxifen. A meta-analysis of the Early Breast Cancer Trialist Collaborative Group showed that 5 years of tamoxifen reduced the recurrence rate by 50% and the mortality rate by a third.[13] However, the success of tamoxifen therapy is variable, and 30% to 45% of patients on tamoxifen relapse or die from recurrent cancer.

Tamoxifen is a **prodrug** and must be metabolized to the active principles to elicit the desired therapeutic effect (Figure 46-2). The lack of efficacy with tamoxifen is explained, in part, by inter-individual differences in the metabolic activation of tamoxifen. The metabolite of tamoxifen with the greatest therapeutic effect is endoxifen, which is formed largely by a reaction mediated by CYP2D6. Patients with impaired CYP2D6 produce less endoxifen than patients with a CYP2D6 EM phenotype.

An individual's CYP2D6 phenotype could be used clinically to qualify patients as good candidates for tamoxifen therapy.[11] For example, patients with a PM genotype are not expected to convert tamoxifen to endoxifen, and they may not respond

appropriately to standard doses of tamoxifen. Detection of the predicted CYP2D6 phenotype prior to therapy may be useful if the patient is a good candidate for an alternate antiestrogen therapy, such as an aromatase inhibitor. Patients prescribed tamoxifen should be counseled regarding the phenocopying effects that occur through drug interactions, particularly with the concomitant use of tamoxifen and a CYP2D6 strong inhibitor (e.g., fluoxetine), that are likely to compromise the efficacy of tamoxifen by inhibiting tamoxifen activation.

Codeine

Codeine is widely used as an antitussive and analgesic medication. Codeine is a prodrug that is activated by CYP2D6-mediated metabolism to morphine. In a typical EM scenario, approximately 10% of the codeine is converted to morphine. A CYP2D6 PM may not activate codeine sufficiently to produce the desirable response and may be best served clinically by selecting a different analgesic agent. In contrast, administration of codeine to a person with the UM phenotype is a significant safety concern, because higher concentrations of morphine than expected lead to risk of unintentional overdose and opioid toxicity. Of particular concern clinically is administration of codeine to a woman who exhibits a CYP2D6 UM phenotype and is breast-feeding. After clinical reports of opioid toxicity in breast-fed newborns of UM mothers, the FDA issued a public health advisory in 2007 warning against codeine administration to mothers with a CYP2D6 UM.[2]

Antidepressant Therapy— Nortriptyline

Antidepressant therapy is challenging because it may require several weeks of drug administration to assess efficacy, and optimizing dose may require many months of trial and error. Most of the antidepressants available today are substrates of CYP2D6, and many are also inhibitors; many case reports of CYP2D6-related toxicity and death have been published. A well-characterized example relates to the tricyclic antidepressants, such as nortriptyline. Nortriptyline is an active drug (and an active drug metabolite of amitriptyline) that is inactivated by CYP2D6-mediated metabolism. When CYP2D6 is impaired, nortriptyline accumulates. High concentrations of nortriptyline are associated with an anticholinergic toxidrome and life-threatening ADRs. Clearance of amitriptyline, nortriptyline, and other tricyclic antidepressants is reduced by at least 50% in PMs of CYP2D6. As shown in Figure 46-3, an individual with a CYP2D6 PM phenotype requires lower doses of nortriptyline than a patient with an EM phenotype to produce similar serum concentrations of active drug.[17]

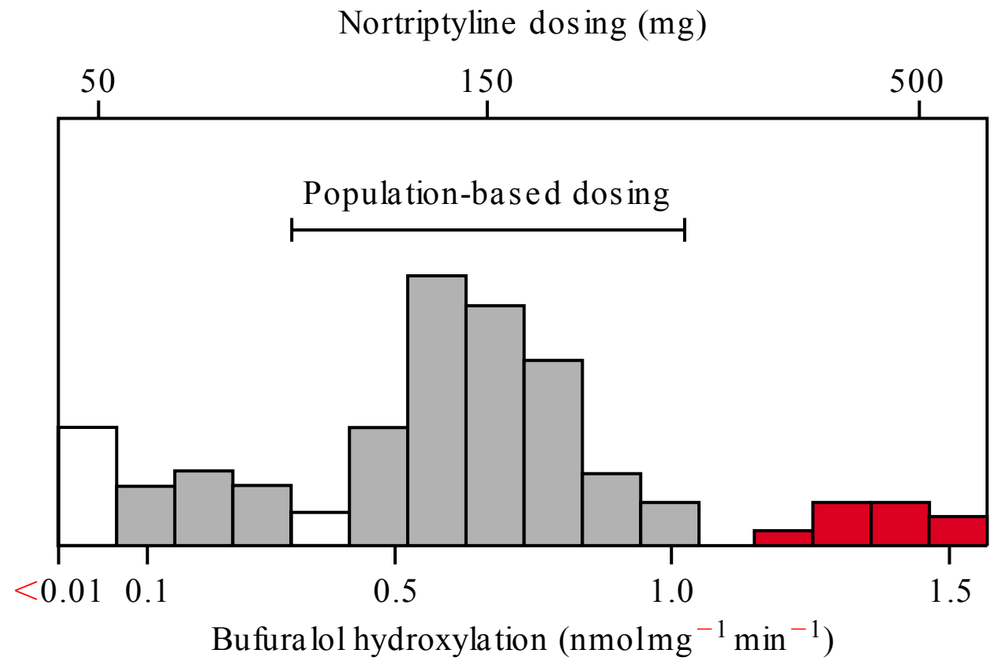

Figure 46-3 Variation in drug metabolism and nortriptyline dosing in the European population, based on cytochrome P450 2D6 (CYP2D6) activity (hydroxylation of bufuralol). Within the population, four phenotypes are identifed: (1) poor metabolizers (PMs), who lack the functional enzyme; (2) intermediary metabolizers (IMs), who are heterozygous for one functional allele or have two partially defective alleles encoding the enzyme; (3) extensive metabolizers (EMs), who have two normal alleles; and (4) ultra-rapid metabolizers (UMs), who carry duplicated or multiduplicated functional CYP2D6 genes. The relative frequency of these phenotypes refers to the European population as a whole. The doses of nortriptyline that are required to achieve therapeutic concentrations in all phenotypes are given. Despite this variation in metabolizing capability, population-based dosing is used today and is based on the average plasma concentrations obtained in a given population for a given dose. (From Ingelman-Sundberg M. Pharmacogenetics of cytochrome P450 and its applications in drug therapy: the past, present and future. Trends Pharmacol Sci 2004;25:193-200. Reproduced with permission from Elsevier.)

Cytochrome P450 2C9

CYP2C9 is a member of the CYP2C family, which includes (1) CYP2C8, (2) CYP2C9, (3) CYP2C18, and (4) CYP2C19. Examples of drugs metabolized by CYP2C9 include (1) warfarin, (2) anticonvulsants, (3) nonsteroidal antiinflammatory drugs (NSAIDs), (4) antidiabetic agents, (5) cholesterol-lowering drugs, and (6) drugs used to treat infection. Like other CYPs, CYP2C9 is subject to inhibition through drug-drug interactions, which affects the phenotype (phenocopying).[14,17]

The CYP2C9 gene is highly polymorphic, and more than 50 allelic variants have been described.[4] However, two variant alleles, CYP2C9*2 and CYP2C9*3, account for most impaired CYP2C9 PM phenotypes. The *2 allele is identified by R144C (430C→T), and the *3 allele is identified by I359L (1075A→C). The allelic frequency of CYP2C9*2 is approximately 15% in Caucasians, and less than 5% in other populations. This allele has not been detected in Asians. The allelic frequency of CYP2C9*3 has been reported as approximately 10% in Caucasians, up to 5% in Asians, and less than 2% in black people. The clinical impact of a CYP2C9*3 variant is more significant than that of a CYP2C9*2 variant due to the greater loss of enzymatic activity associated with the CYP2C9*3 variant. No UM genotype or phenotype has been described for CYP2C9.

Several protocols have been published or are available commercially for detecting variants in this gene. Most focus on detection of only the *2 and *3 alleles, as well as the common promoter variant of another gene, VKORC1, due to the complimentary utility in identification of patients at risk for warfarin sensitivity. The warfarin application of CYP2C9 genotyping is described in more detail later, with VKORC1, a gene associated with pharmacodynamics of warfarin response. Other clinical applications of CYP2C9 and VKORC1 genotyping are not routine.

Cytochrome P450 2C19

CYP2C19 is involved in the metabolism of a number of therapeutic drugs, including (1) clopidogrel, (2) citalopram, (3) diazepam, (4) omeprazole, (5) propranolol, and (6) proguanil. Known metabolizer phenotypes are (1) PM, (2) IM, (3) EM, and (4) UM.3,514,17 With CYP2C9, there are two common alleles, CYP2C19*2 and CYP2C19*3, that account for nearly all PMs. The PM phenotype occurs in 2% to 5% of Caucasian and Black populations, and 10% to 23% of Asian populations. The CYP2C19*2 arises from a 681G→A mutation, which results in a splicing defect and essentially no enzyme activity. The second most common CYP2C19 allele (CYP2C19*3) associated with the PM phenotype results from a single nucleotide substitution, 636G→A, which produces a premature stop codon and no active enzyme product, but allele frequencies are less than 1% in most populations. The CYP2C19*17 arises from a promoter variant in the gene (-806C→T); it is present in nearly 40% of Caucasians, Blacks, and Asians; and is associated with a UM phenotype. Several protocols have been published for detecting variants in CYP2C19, most of which focus on detection of the *2, *3, and *17 alleles.

Examples of the pharmacogenomic application of CYP2C19 are in the administration of clopidogrel and antidepressants.

Clopidogrel

Clopidogrel is a common drug prescribed to inhibit platelet aggregation, often in combination with aspirin. Approximately one third of patients do not respond to clopidogrel. One explanation for drug resistance is that clopidogrel is a prodrug that requires metabolism to the active metabolite, prasugrel. Carriers of the CYP2C19*2 and *3 alleles have reduced formation of the active metabolite, and they have a higher incidence of major thrombotic events. It is recommended that patients who carry one or more copies of the CYP2C19*2 allele consider an alternative therapy, such as prasugrel itself.[16]

Antidepressant

Genotyping of CYP2C19 may be complimentary to genotypoing of CYP2D6 for explaining inappropriate responses to antidepressant medications. For example, CYP2C19 is the primary enzyme responsible for converting amitriptyline to its active metabolite nortriptyline. Monitoring serum or plasma concentrations of both amitriptyline and nortriptyline is also used to guide amitriptyline therapy. Although CYP2D6 is thought to be more relevant clinically than CYP2C19 for most antidepressants, CYP2C19 becomes very important for a drug that is a substrate of both CYP2D6 and CYP2C19 when CYP2D6 is impaired or deficient, particularly if the CYP2C19*17 is present.

Phase II Enzymes

Phase II reactions typically involve enzymes that conjugate drug analytes with (1) acetyl, (2) glucuronyl, (3) amino acyl, or (4) sulfate groups. In general, these enzymes are not typically induced or inhibited to the same degree as CYPs. However, exhausting the substrates or cofactors that are transferred prevents the corresponding transferase reactions from occurring.

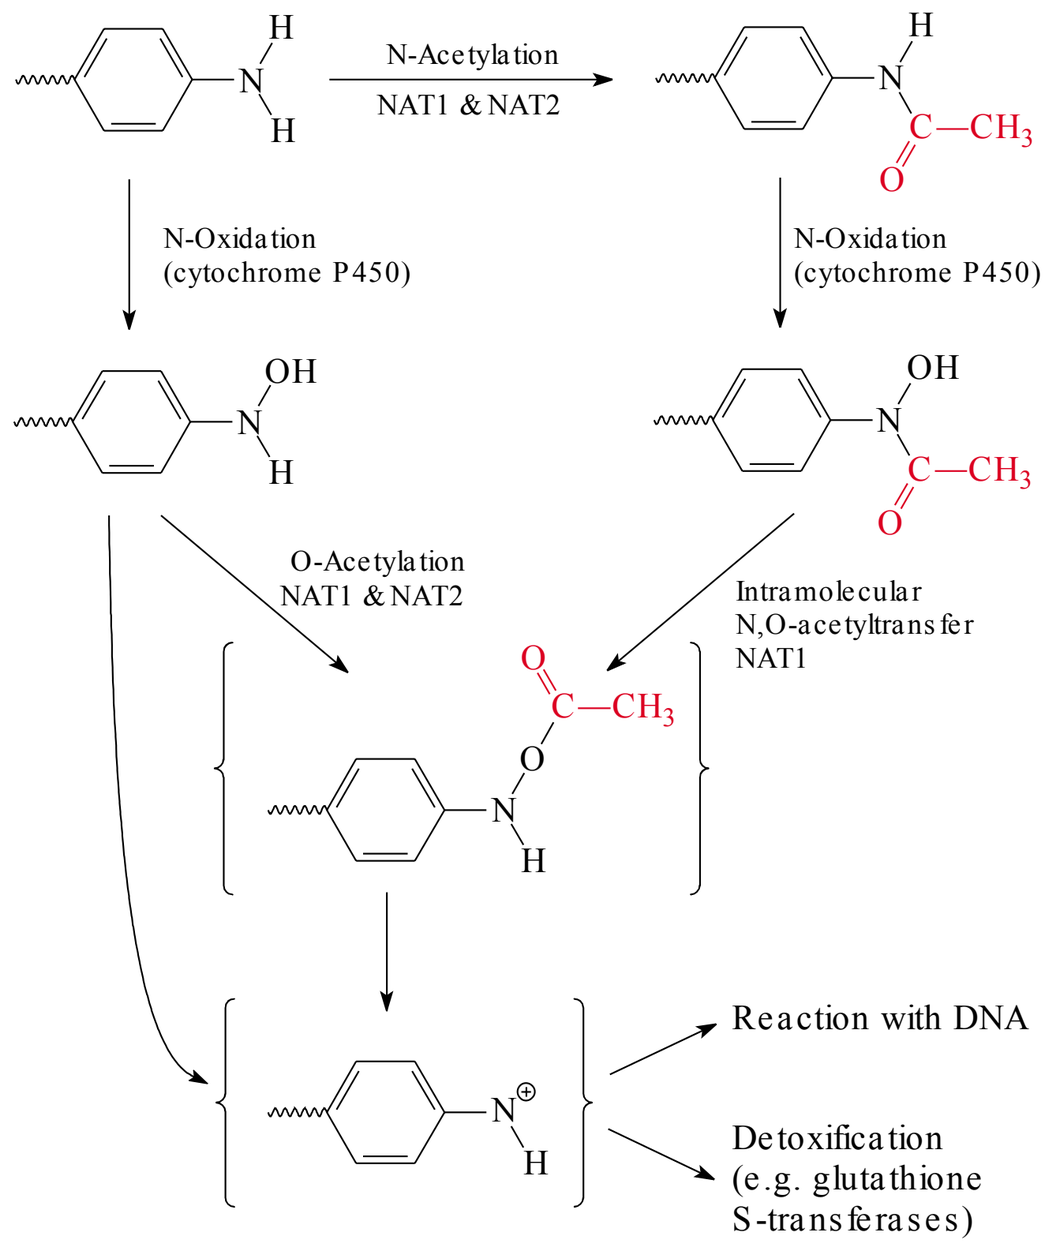

Figure 46-4 Schematic view of the role of N-acetyltransferase (NAT) enzymes in the metabolism of aromatic amines. N-acetylation might be a detoxifcation reaction in a number of cases; however, after N-hydroxylation of aromatic amines (e.g., by cytochrome P450 [CYP] enzymes), NAT enzymes are able to bioactivate these intermediates by O-acetylation or by intramolecular N,O-acetyltransfer, leading to the formation of nitrenium ions, which might react with DNA or alternatively be detoxifed by, for example, glutathione s-transferase enzymes. It is shown that a number of other biotransformation enzymes are involved in the metabolism of aromatic amines as well. (Redrawn from Wormhoudt LW, Commandeur JNM, Vermeulen NPE. Genetic polymorphisms of human N-acetyltransferase, cytochrome P450, glutathione-S-transferase, and epoxide hydrolase enzymes: relevance to xenobiotic metabolism and toxicity. Crit Rev Toxicol 1999;29:59-124. Reproduced by permission from Taylor and Francis, Inc.)

Like phase I enzymes, phase II enzymes are synthesized from genes that are classified into families and further into subfamilies based on homology. These include (1) **N-acetyltransferases (NATs)**, (2) **thiopurine S-methyltransferases (TPMTs)**, (3) **uridine 5′-diphosphate (UDP) glucuronosyltransferases (UGTs)**, and (4) dihydropyrimidine dehydrogenases (DPDs).

N-acetyltransferase

The N-acetyltransferases (NAT) slow acetylator is one of the earliest-described pharmacogenetic phenotypes. NAT1 and NAT2 are two thoroughly-characterized isoforms that catalyze the transfer of an acetyl moiety from acetyl-coenzyme A (CoA) to homocyclic and heterocyclic arylamines and hydrazines (Figure 46-4). Substrates of these phase II reactions include (1) drugs, (2) carcinogens, (3) toxicants, and (4) possibly endogenous compounds. NAT status has been implicated

in predisposing to ADRs, and it has also been associated with risk of diseases, including immunologic disorders and several cancers. NAT substrates also have been related to (1) cigarette smoking, (2) some medications, and (3) occupational exposures.

The NAT1 and NAT2 genes share 87% nucleotide sequence identity and 81% amino acid sequence identity. Many variant alleles have been described, and a consensus nomenclature has been published.[18] NAT1*3 and NAT2*4 are considered the wild-type alleles. The NAT1*10 is the most common variant NAT1 allele in many human populations, but the phenotype-genotype relationship is not well defined. For NAT2, the (1) *5, (2) *6, (3) *7, (4) *13, and (5) *14 alleles are thought to account for more than 99% of slow acetylator phenotypes.

NAT2 slow acetylators are common in many populations, including approximately 80% of Egyptians; 50% of Caucasians, Europeans, and Blacks; 20% of Asians; and 5% of Canadian Inuits.[17] Genotyping and phenotyping methods predict NAT phenotype; neither genotyping nor phenotyping methods are widely available to support routine clinical testing today.

Thiopurine S-Methyltransferase

Thiopurine S-methyltransferase (TPMT) is a phase II metabolic enzyme that catalyzes the inactivation of 6-mercaptopurine (6-MP) by S-methylation, thus preventing it from forming the thioguanine nucleotides (TGNs) that are responsible for the activity of 6-MP. It also affects azathioprine (AZA) metabolism, because AZA is another prodrug that is metabolized to 6-MP (Figure 46-5). Endogenous substrates for TPMT are currently unknown. AZA and 6-MP are used in the therapeutic management of leukemia, particularly **acute lymphoblastic leukemia (ALL)** in children, but they are also used to treat a diverse range of conditions, including treatment of autoimmunce conditions (such as rheumatoid arthritis and inflammatory bowel disease) and prevention and treatment of rejection of transplanted solid organs. These agents are cytotoxic, acting via incorporation of TGN into DNA. Outside the bone marrow, these agents are oxidatively inactivated by xanthine oxidase or methylated by TPMT. In hematopoietic tissue, however, the effect of xanthine oxidase is negligible, leaving TPMT as the only significant inactivation pathway. Hematopoietic tissues are therefore susceptible to damage in cases in which TPMT activity is very low. TPMT activity is highly variable in all large populations studied to date; approximately 90% of individuals have high activity, 10% have immediate activity, and 0.3% have low or undetectable enzyme activity. Numerous studies have shown that TPMT-deficient patients are at high risk for severe, and sometimes fatal, toxicity.[17]

The (1) *2, (2) *3A, (3) *3B, and (4) *3C alleles of TPMT, account for 80% to 95% of intermediate or low enzyme activity cases in most ethnic groups (see Figure 46-5). The *3A allele is most common in Caucasians, and *3C is most common in Blacks and in Asian populations. The TPMT *2 and *3B alleles are rare in comparison with TPMT*3A or *3C. The relationship between phenotype and genotype is very good for most patients, as illustrated in Figure 46-6.

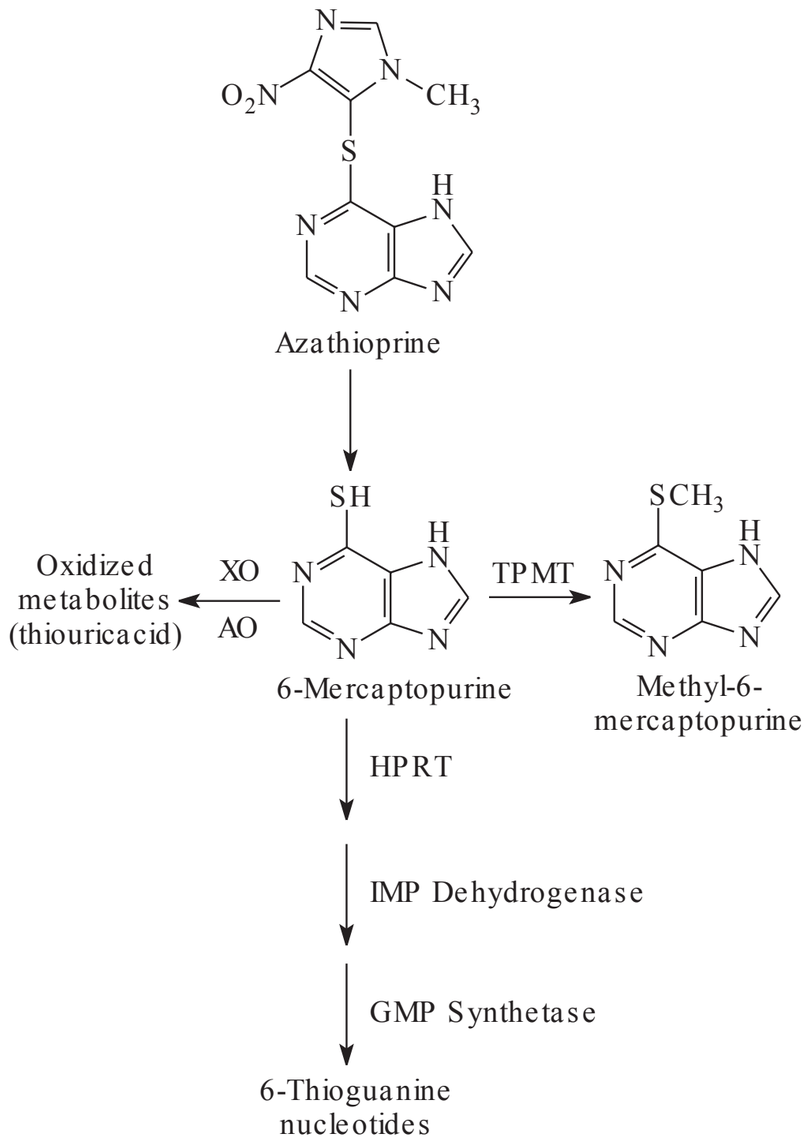

Figure 46-5 Simplifed metabolic pathway for prodrug thiopurines, azathioprine (AZA) and 6-mercaptopurine (6-MP). AO, Aldehyde oxidase; GMP, guanine monophosphate; HPRT, hypoxanthine phosphoribosyltransferase; IMP, inositol monophosphate; TPMT, thiopurine S-methyltransferase; XO, xanthine oxidase.

There are at least three approaches to TPMT testing: (1) biochemical phenotyping by determination of TPMT activity within erythrocytes from the patient before administration of drug, (2) metabolic phenotyping by measurement of the concentrations of 6-MP and metabolites in the blood after drug administration, or (3) genotyping. Biochemical phenotyping is limited to patients who have not received a blood transfusion over the weeks previous to TPMT testing and who have healthy red blood cells at the time of testing (often not the case at the time ALL is diagnosed). Metabolic phenotyping requires that AZA or 6-MP be administered before testing. This approach is therefore most useful for optimizing dose once steady-state concentrations have been achieved, or for troubleshooting for patients who have experienced toxicity or an ADR. Genotyping is valid anytime, as long as the patient genotype is detected by the analytical technique employed.

The influence of TPMT genotype on hematopoietic toxicity is most dramatic for homozygous variant patients, but it is also of clinical relevance for heterozygous individuals. The labeling for 6-MP was revised in 2004 to include TPMT testing options. It is advised that patients who are TPMT PMs either seek alternative therapies, or receive only 5% to 10% of the conventional dose with careful monitoring. For patients who are predicted to be TPMT IMs, a dose reduction of 30% to 70% has been recommended, depending on the specific clinical scenario.

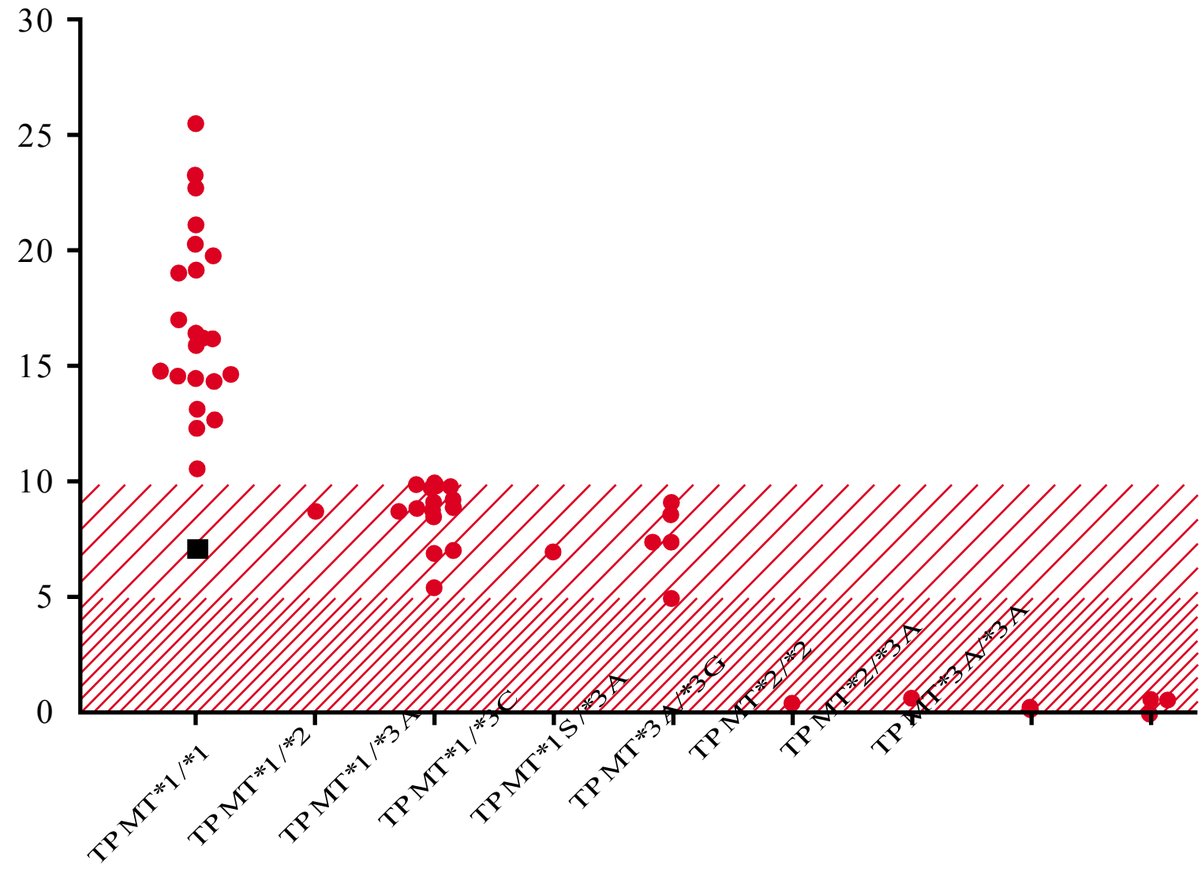

Figure 46-6 Thiopurine S-methyltransferase (TPMT) activity as related to genotypes determined by mutation-specifc polymerase chain reaction methods. The heavily shaded area depicts the range of TPMT activity in erythrocytes that defnes TPMT defciency (5 U/mL of packed red blood cells); the lightly shaded area depicts intermediate activity that defnes TPMT heterozygous phenotypes (5 to 10 U/mL of packed red blood cells); and the nonshaded area depicts the range of TPMT activity in patients who have homozygous wild-type phenotypes. Red circles indicate patients with concordant genotype and phenotype; the black square indicates one patient with discordant genotype and phenotype (TPMT*1/*1). (From Yates CR, Krynetski EY, Loennechen T, Fessing MY, Tai HL, Pui CH, et al. Molecular diagnosis of thiopurine S-methyltransferase defciency: genetic basis for azathioprine and mercaptopurine intolerance. Ann Intern Med 1997;126:608-14. UDP-Glucuronosyltransferase 1A1

The mammalian uridine 5′-diphosphate **(UDP)-glucuronosyltransferase (UGT)** is a superfamily comprised of more than 100 members. The UGT1 and UGT2 families are most efficient at glucuronidation of drugs and toxicants in humans. The UDP-glucuronosyltransferase 1A1 (UGT1A1) isoform has been of greatest interest clinically. The primary goal of glucuronidation is to increase the water solubility of a compound, which typically inactivates that compound and promotes its elimination. An important endogenous substrate for UGT1A1 is bilirubin. Impairment of UGT1A1 leads to accumulation of bilirubin. UGT1A1 is also involved in the glucuronidation of drugs. Impairment of UGT1A1-mediated glucuronidation of drugs was first recognized in patients with **Gilbert syndrome** who were administered **irinotecan**. An inverse relationship between expression of UGT1A1 and bilirubin concentration was recognized in patients with Gilbert syndrome and ultimately led to recognition of variation in the promoter region of the gene.[17]

UGT1A1 is the most 3′ of the UGT1A isoform genes. More than thirty SNPs that lead to nonfunctional UGT1A1 have been identified, but the number of TA repeats found in the TATA sequence of the UGT1A1 promoter region dramatically afects expression of the gene. The number of TA repeats in unafected Caucasians is 6, which is described as (TA)6 or UGT1A1*1. The most common variant of this sequence is the presence of seven repeats, known as (TA)7 or UGT1A1*28, and this leads to a 30% reduction in promoter activity of the UGT1A1 and a subsequent reduction in transcription.[9] Tests for detection of UGT1A1*28 are commercially available. Both (TA)5 and (TA)8 variants of this sequence, although relatively rare, are recognized to exist and correlate with higher and lower expression, respectively, than the (TA)6,. Genotypes are typically referred to as 6/6 for no variants, or 7/7 for homozygosity of UGT1A1*28. The UGT1A1*28 allele is observed in approximately 40% of Caucasians and blacks.

A thoroughly-studied example of a pharmacogenetic application for UGT1A1*28 genotyping is seen with irinotecan. Irinotecan is widely used in metastatic colorectal cancer and in other tumors, such as lung and liver. It is a prodrug and is converted to its active, cytotoxic metabolite SN-38. Approximately 20% to 35% of patients accumulate SN-38 and experience dose-limiting and potentially life-threatening (grade 3 or 4) diarrhea and/or neutropenia when treated with irinotecan. A major route for inactivation of SN-38 is formation of the glucuronide conjugate by UGT1A1. Individuals possessing variant TA repeats in UGT1A1 are susceptible to toxicity with irinotecan. It is generally recommended that patients with the TA7/7 genotype receive a reduced dose of irinotecan, although specific dosing guidelines are lacking, and the efect is probably most relevant only in “high dose” irinotecan regimens.

Dihydropyrimidine Dehydrogenase

DPD, coded from DPYD, is the initial and rate-limiting enzyme in the three-step pathway of uracil and thymidine catabolism and in the pathway leading to formation of β-alanine. It is also responsible for degrading fluoropyrimidines, such as the commonly-used cancer chemotherapeutic drugs, fluorouracil and capecitabine. Under typical metabolic conditions, approximately 80% of 5-fluorouracil is inactivated by DPD. Patients who are homozygote for deleterious DPYD variants should seek alternative treatment, or reduce the dose of 5-flurouracil significantly, to minimize the incidence of severe and sometimes life-threatening toxicity.[17]

Genes Associated with Pharmacodynamics

Vitamin K Epoxide Reductase Complex 1

Vitamin K epoxide reductase (VKOR), a key enzyme in the vitamin K cycle, is encoded by the gene named VKOR complex, subunit 1 (VKORC1). VKOR converts vitamin K epoxide to vitamin K and is the primary site of action for the commonly-used oral anticoagulant warfarin. VKOR thus is a component of warfarin pharmacodynamics, rather than of warfarin metabolism. Impairment of VKOR therefore limits its activation of the vitamin K–dependent coagulation factors and explains the anticoagulation effect of warfarin. The amount of VKOR expressed, which may be genetically controlled, dictates a person's sensitivity to warfarin.

More than thirty VKORC1 variants have been described, but most clinical testing detects only the promoter variant of VKORC1 (−1639G→A). The variant is strongly linked (through linkage disequilibrium; see Chapter 47) with known warfarin-sensitive genotypes and haplotypes.

Warfarin is an anticoagulant drug given to control the formation of blood clots. Individual response to warfarin is highly variable, and the drug is implicated in life-threatening adverse events. Administration of excess warfarin leads to bleeding, and too little warfarin fails to prevent blood clots. In routine clinical practice, the dose for individual patients is adjusted to achieve a target therapeutic **International Normalized Ratio (INR)**, usually between 2 and 3. INR is calculated from the prothrombin (clotting) time (PT) of blood samples. Factors known to affect warfarin dose requirements include (1) clinical factors, (2) dietary factors, (3) concomitant medications, and (4) genetics. These sources of variability are discussed in detail in the 2008 practice guidelines published by the American College of Chest Physicians, as well as in the product labeling for the popular formulation of warfarin sold as Coumadin.[1]

Genetic variants of VKORC1, representing sensitivity in response to warfarin, and of CYP2C9, representing pharmacokinetics of warfarin inactivation, are thought to account for approximately one third of the variability among patients. When the genetic variants are combined with common clinical factors and early INR data, up to 70% of the variability seen among patients is thought to be explained. Among the many mathematical algorithms published for predicting warfarin dose, consistently included predictors (covariates) include age, gender, an index of body size, the three common genetic variants: CYP2C9*2, CYP2C9*3, and the promoter variant of VKORC1 (−1639G→A). Some algorithms account for factors such as (1) smoking status, (2) common interfering co-medications (e.g., amiodarone), (3) liver disease, and (4) existing INR data. Comparisons of several published algorithms demonstrate good agreement in predicting maintenance dose requirements, and the International Warfarin Pharmacogenetics Consortium indicates that pharmacogenetics-guided management of ers improved outcomes over fixed dose or clinical monitoring alone, particularly for people who require low doses.[7] Clinical consensus has not been achieved, however, for application of pharmacogenetic data and related dosing algorithms in routine warfarin initiation and management.

Human Leukocyte Antigen Complex, Class I, B

The HLA complex is a cornerstone for the immune system because of its involvement in identification of foreign proteins. HLA is the human version of the major histocompatibility complex (MHC), a gene family common to many species. The HLA proteins produced from these genes are expressed on the surface of nearly all cells, where they bind to peptides that are exported from the cell. These peptides are thereby captured and displayed to the circulating cells of the immune system. If the immune system recognizes the peptides as foreign (e.g., viral or bacterial peptides), it responds by triggering the infected cell to self-destruct. This process contributes to the toxicity of drugs such as abacavir.

The MHC in humans consists of more than 200 genes that are categorized into three groups: class I, class II, and class III. Humans have three major class I genes, known as HLA-A, HLA-B, and HLA-C. It is the HLA-B gene, and in particular, the HLA-B*5701 allele, that has been best characterized from the perspective of pharmacogenetics, based on association of variants with drug hypersensitivity phenotypes. HLA-B gene variants are also associated with risk of disease, particularly immune-mediated inflammatory disease.

Severe cutaneous adverse reaction syndromes (SCARS), such as **Stevens-Johnson syndrome (SJS)** and **toxic epidermal necrolysis (TEN)**, lead to extremely painful rashes that sometimes are life-threatening. Drug-induced hypersensitivity reactions like SCARS are associated with several drugs. A thoroughly-characterized HLA-drug association is the one between HLA-B*5701 and abacavir. Abacavir is a reverse transcriptase inhibitor used to treat HIV infection. Approximately 10% of Indian, 5% to 8% of Caucasians, and 2% to 3% of black people treated with abacavir develop a SCARS-like reaction during the first 6 weeks of therapy. Abacavir binds to the peptide binding groove of HLA-B*5701, and the binding changes the self-peptides that are presented to the immune system. The change leads to immune-mediated destruction of the cells. The reaction to abacavir is not dose-dependent and requires permanent discontinuation of the drug. Future exposure to abacavir, in a sensitive individual that was previously exposed, may precipitate a life-threatening reaction due to sensitization.

Genetic testing to detect the HLA-B*5701 allele varies among laboratories, ranging from complete gene sequencing to identification of single SNPs in related genes (genes in linkage disequilibrium with HLA-B*5701, such as HCP5). Phenotyping for abacavir is also available, such as through flow cytometric analysis. Due to the high positive predictive value of HLA-B*5701 identification, pre-therapeutic testing to detect patients at risk for abacavir hypersensitivity was incorporated into the 2008 guidelines for the use of antiretroviral agents in HIV-1 infected adults and adolescents, published by the Office of AIDS Research Advisory Council, and it has been shown to be medically useful and cost-effective.[5,12]

Review Questions

1. The acronym "SNP" stands for
   a. single-nucleotide polymorphism.
   b. single native protein.
   c. singlet nuclear proteomic.
   d. single-gene normal phenotype.
2. Pharmacogenetics is defined as
   a. entry level human genetics for pharmacists.
   b. the study of genetic polymorphisms as revealed by drug responses.
   c. the study of the genetics of human drug metabolism.
   d. the study of human disease susceptibility genes.
3. The response to which one of the following drugs is affected by the cytochrome P450 2D6 (CYP2D6) polymorphism?
   a. Warfarin
   b. Omeprazole
   c. Codeine
   d. Nicotine
4. A phase II enzyme acts on a substrate to
   a. conjugate it with an acetyl or sulfate group.
   b. oxidize it.
   c. stabilize it so that metabolism will not occur.
   d. modulate its binding to a receptor.
5. A drug that is administered in an inactive form that must be metabolized before it has an effective action is referred to as a(n)
   a. cytochrome P450 (CYP) enzyme.
   b. poor metabolizer (PM).
   c. antidrug.
   d. prodrug.
6. The acronym "ADR" stands for
   a. ability to drive reaction.
   b. allelic diversity response.
   c. adverse drug reaction.
   d. allele-driven result.
7. An example of a phase I enzyme is
   a. thiopurine S-methyltransferase (TPMT).
   b. cytochrome P450 2C9 (CYP2C9).
   c. N-acetyltransferase 1 (NAT1)
   d. human leukocyte antigen complex, class I, B (HLA-B)
8. How a drug elicits responses and whether the response is desirable or undesirable is described by which one of the following?
   a. Pharmacodynamics
   b. Pharmacokinetics
   c. Phenocopying
   d. Pharmacogenetics
9. The inherited instructions an individual carries within their genetic code is referred to as their
   a. phenotype.
   b. phenocopy.
   c. genotype.
   d. metabolizer status.
10. Nonsteroidal antiinflammatory drugs (NSAIDs), such as ibuprofen or aspirin, are metabolized by which one of the following enzymes?
    a. N-acetyltransferase 2 (NAT2)
    b. UDP-glucuronosyltransferase 1A1 (UGT1A1)
    c. cytochrome P450 2C19 (CYP2C19)
    d. cytochrome P450 2C9 (CYP2C9)

CHAPTER 47

Principles of Molecular Biology

Y. M. Dennis Lo, M.A., D.M., D. Phil., F.R.C.P., F.R.C. Path., F.R.S.,
and Rossa W. K. Chiu, M.B.B.S., Ph.D., F.R.C.P.A., FHKAM (Pathology)

Objectives

1. Define the following:
   - Allele
   - Chromatin
   - Chromosome
   - Circulating nucleic acids
   - Codon
   - Epigenetics
   - Exon
   - Gene
   - Genetic code
   - Genome
   - Genotype
   - Intron
   - Nucleic acid
   - Nucleotide
   - Phenotype
   - Semiconservative
2. Describe the essential aspects of molecular biology, including functions of DNA and RNA, transfer of genetic information from parent to daughter cell, content of the human genome, and uses of genotyping and phenotyping.
3. Discuss the similarities and differences between DNA and RNA, including physical and chemical structure, physiologic function, and uses in clinical diagnostic testing; compare the structure and functions of messenger RNA (mRNA), transfer RNA (tRNA), and ribosomal RNA (rRNA).
4. State the structure, chemical composition, and chemical bonds (if any) of purines and pyrimidines, bases and base-pairs, nucleotides and DNA strands; calculate the percentage of nucleotides present in a genome given appropriate information.
5. Draw a nuclear chromosome, including position of telomeres and centromeres; compare telomeres and centromeres, including function and location on a chromosome.
6. Describe the physical structure and chemical composition of chromatin during its dynamic changes during the cell cycle and including histone interaction with DNA; state the importance of chromatin in packing of DNA into chromosomes; compare euchromatin and heterochromatin, including structure, function, and specific location in a chromosome.
7. For each of the following processes, list the steps of the process, where they occur within a eukaryotic cell, the proteins involved, and events occurring in each step:
   - DNA replication
   - RNA transcription and processing
   - mRNA translation
8. State the specific physiologic functions of DNA polymerase and RNA polymerase II.
9. For each of the following epigenetic phenomena, state the function, biochemical interactions, and significance in gene expression:
   - DNA methylation
   - Histone modification
   - Nucleosome positioning and remodeling
10. Describe non-coding RNAs, including biogenic pathway (if known), structure, and known or purported function.
11. Compare the mitochondrial genome to nuclear DNA, including structure, cellular location, inheritance, and packaging.
12. For the following projects, list the general aims and current state of completion or outcome:
    - 1000 Genomes Project
    - ENCODE
    - Human Epigenome Project
    - Human Genome Project
    - International HapMap Project

Key Words and Definitions

Allele One of the alternative versions of a gene at a given location (locus) along a chromosome. An individual inherits two alleles for each gene, one from each parent. Alleles may demonstrate sequence variations that determine variations in the functional characteristics of a gene product (e.g., translated protein).

Argonaute proteins Proteins of the RNA-induced silencing complex (RISC), the complex responsible for the gene silencing process known as RNA interference (RNAi).

Autosome A nonsex chromosome; there are 22 pairs of autosomes in the human genome.

Key Words and Definitions—cont'd

Base pair A purine and a pyrimidine nucleotide bound by hydrogen bonds; in DNA base pairing, adenine binds to thymine and guanine pairs with cytosine; in RNA, uracil replaces thymidine for base pairing.

CentiMorgan (cM) A unit of measure that refers to the distance between two gene loci determined by the frequency with which recombination occurs between them. Two loci are said to be one cM apart if recombination is observed between them in 1% of cell division cycles.

Centromere A primary constriction in a chromosome; centromeres play an important role in directing the movement of chromosomes between daughter cells during cell division.

Chromatin Nuclear DNA and its associated structural proteins; chromatin is arranged and organized in a hierarchical fashion in which the degree of its condensation increases with higher levels of structural organization.

Chromosome A highly-ordered structure of a single double-stranded DNA (dsDNA) molecule, compacted many times with the aid of structural DNA-binding proteins.

Codon A three-nucleotide sequence that "codes" for an amino acid during translation; there are 64 possible codons in nuclear DNA.

Deoxyribonucleic acid (DNA) A molecule that carries genetic information and is a double-stranded polymer of nucleotides.

DNA-binding proteins Proteins that recognize and bind to specific DNA sequences. Some DNA-binding proteins are involved in the regulation of DNA transcription.

DNA methylation The addition of a methyl group typically to the fifth carbon position of cytosine residues in CpG dinucleotides; this epigenetic process is implicated in growth and development of organisms.

DNA methyltransferase (DNMT) Any of a group of enzymes that catalyze the transfer of a methyl group from S-adenosylmethionine to a specific nucleotide in a DNA molecule, with different enzymes acting on specific nucleotides and positions of methylation.

Drosha A Class 2 RNase III enzyme responsible for processing of microRNA (miRNA).

Epigenetics Processes that alter gene function or its interpretation by mechanisms other than those that rely on changes in DNA sequences; these processes include DNA methylation, genomic imprinting, histone modification, and chromatin remodeling.

Euchromatin Genomic regions that are rich in genes and are, in general, less compactly organized during interphase.

Eukaryote Organisms such as higher plants and animals, fungi, protozoa, and most algae; they have a true nucleus bounded by a nuclear membrane within which lie the chromosomes.

Exon The coding region of a gene that will be expressed as protein following translation.

Exonuclease A nuclease that releases one nucleotide at a time (serially) beginning at one end of a nucleic acid; exonuclease activity excises incorrectly paired nucleotides during replication.

Gene A unit of DNA that specifies production of proteins and RNA molecules required for cellular function.

Genetic code The complete list of nucleotide codons and the amino acids or actions they "code" for.

Gene expression The process responsible for the flow of genetic information from gene to protein.

Genome The complete set of chromosomes; the total complement of hereditary information; the human genome contains two copies, termed alleles, of each autosomal gene. One half of the genome is inherited from each parent and is termed the haploid genome. The complete genome inherited from both parents is termed the diploid genome.

Genotype The primary nucleotide sequences of the two gene alleles.

Heterochromatin Genomic regions that are gene poor or span transcriptionally silent genes and are more densely packed during interphase.

Heteroplasmy The presence of more than one population of mitochondrial DNA sequences in a cell consequent to the accumulation of sequence variations.

Histones A class of structural proteins involved in the three-dimensional organization of nuclear DNA.

Homoplasmy The presence of a homogeneous population of mitochondrial genomes in a cell.

Human Genome Project A project undertaken by the International Human Genome Sequencing Consortium to decipher the three billion base pairs in the human genome; the project was completed in 2003.

Interphase The period between cell divisions.

Intron A noncoding region of a gene, locked between exons, that will not be translated into protein.

Leber's hereditary optic neuropathy (LHON) A neuropathy transmitted from mother to children that is characterized by a degeneration of retinal ganglion cells (RGCs) and their axons that leads to a loss of central vision.

Linkage disequilibrium Nonrandom association of alleles at different loci; the rate reflects rates of recombination and is used as a measure of distance between the loci. See centiMorgan.

MicroRNA (miRNA) Short noncoding RNA (ncRNA) molecules around 22 nucleotides in length that play a role in regulation of gene expression by interfering with effective translation of mRNA to proteins.

Mitochondrial DNA The circular DNA within a mitochondrial organelle that codes for polypeptides involved in the oxidative phosphorylation pathway; this DNA is typically transmitted across generations by maternal inheritance.

Nucleases Enzymes that catalyze the hydrolysis of nucleic acid by cleaving chains of nucleotides into smaller units.

Nucleic acid A polymer made of nucleotide monomers (a sugar moiety, a phosphoric acid, and purine or pyrimidine bases); examples are deoxyribonucleic acid (DNA) and ribonucleic acid (RNA).

Nucleosome A unit of chromatin consisting of nucleosome core particles (146 base pairs of double-stranded DNA [ds-DNA]) wound around a core of eight histone proteins; technically, a nucleosome also includes a linker DNA between nucleosomes, but the word often is used to mean the core particle.

Nucleotide A unit of DNA or RNA, consisting of one chemical base (purine or pyrimidine) plus a sugar molecule (deoxyribose or ribose) and at least one phosphate group.

Key Words and Definitions—cont'd

Okazaki fragment A relatively short fragment of DNA (with no RNA primer at the 5′ terminus) created on the lagging strand of DNA during DNA synthesis.

Phenotype The observable characteristics of an organism, including visible features (eye color, height) and chemical and behavioral characteristics; reflects interaction of genes and environment.

Polymerase Enzymes involved in DNA replication and transcription; DNA polymerase episilon reads a parent DNA template and attaches nucleotides to a growing daughter strand according to the base-pairing rules of double-stranded DNA (ds-DNA); RNA polymerase II binds to a promoter region of a DNA strand to initiate transcription.

Polymerase chain reaction (PCR) An in vitro method for exponentially amplifying DNA.

Prokaryote Oganisms (such as bacteria) that are characterized by the absence of a distinct, membrane-bound nucleus or membrane-bound organelles and by DNA that is not organized into chromosomes.

Promoter A regulatory region of DNA that serves to bind RNA polymerase II that in turn binds other substances that will lead to initiation of transcription; promoters and the substances that bind to them control the rate and timing of tRNA synthesis and thus of synthesis of the coded protein.

Purine A base containing two carbon-nitrogen rings; adenine and guanine are purines.

Pyrimidine A base containing one carbon-nitrogen ring; cytosine, thymine, and uracil are pyrimidines.

Recombination The process of exchange of genes or segments of DNA between chromosomes; recombination produces gametes with chromosomes that are different from the parent's. Reombination of DNA segments is also done in the laboratory as a step in prodcing recombinant proteins (see centiMorgan).

Replication The faithful reproduction of the DNA content from parent to daughter cells during cell division.

Ribonucleic acid (RNA) A biological substance similar to DNA with the exceptions of being single stranded, containing ribose as the sugar moiety, having an extra hydroxyl group, and containing uracil instead of thymine; there are different functional types of RNA, including messenger (coding) RNA (mRNA), ribosomal RNA (rRNA), transfer RNA (tRNA), and other small noncoding RNAs (ncRNAs), such as microRNA (miRNA).

Ribosome A large molecular structure comprised of ribosomal RNA and protein that is found in the cytoplasm of cells that serves as the site of protein synthesis.

Spliceosome A large ribonucleoprotein complex, composed of various small nuclear ribonucleoproteins (snRNP) as well as other protein factors; it attaches to specific sites on pre-mRNA and catalyzes splicing out of their introns in the formation of mature mRNA.

Telomere The DNA sequences at the end of a chromosome; telomeres contain repetitive nucleotide sequences that protect the ends of chromosomes from recombination with other chromosomes.

Tiling arrays A subtype of microarray that functions by hybridizing labeled DNA or RNA target molecules to probes fixed onto a solid surface.

Transcription The process of transferring sequence information from the gene regions of DNA to a messenger RNA molecule.

Translation The process whereby an mRNA sequence forms an amino acid sequence with the help of tRNA and eventual enzymatic peptide bond formation between amino acids to synthesize polypeptides; translation occurs on cytoplasmic ribosomes.

Molecular diagnostics represents one of the most rapidly developing areas within many diagnostic disciplines, including (1) clinical chemistry, (2) clinical hematology, (3) clinical immunology, (4) clinical microbiology, and (5) tissue pathology. Advances in the field have been made possible by improved understanding of molecular biology and genetics and of their relationships with human diseases and the development of powerful technologies for the analysis of **nucleic acids**. The fundamental concepts in molecular biology are reviewed in this chapter.

Landmark Developments in Genetics and Molecular Diagnostics

Significant events that occurred in the late 20th century include (1) decoding of the human **genome**, (2) cloning of organisms, and (3) progress in stem cell research and **gene** therapy. Many of these advances would not have been possible without the many earlier landmark discoveries that unveiled the mysteries of genetics and paved the way for modern molecular diagnostics.[5] Genetics began modestly when Mendel experimented with garden peas. His findings, published in 1866 and suggesting the concepts of **alleles** and genes as discrete units of heredity, essentially captured the most fundamental concepts in inheritance. In 1910 Morgan revealed that the units of heredity are contained within **chromosomes**, but it was Avery in 1944 who confirmed through studies on bacteria that it was **deoxyribonucleic acid (DNA)** that carried the genetic information. Franklin and Wilkins studied DNA by x-ray crystallography, which subsequently led to unraveling of the double-helical structure of DNA by Watson and Crick in 1953. In the 1960s Smith demonstrated that DNA can be cleaved by restriction enzymes, which Arber had discovered earlier. This is facilitated the subsequent development of recombinant DNA technologies. Nathans furthered the work on restriction enzymes and was the first to construct a genetic map. In 1975 the Southern

blot was invented, which allowed the detection of specific DNA sequences. Soon after, in 1977, DNA-sequencing methods were developed, and the first complete DNA sequence of an organism, a bacteriophage, was published. Prenatal genetic diagnosis of sickle cell disease was first shown to be feasible by Kan and Chang in 1978. In 1985 Mullis and co-workers developed the **polymerase chain reaction (PCR)**, which provided a rapid way to make many copies of a DNA molecule. The existence of functional small noncoding RNAs (ncRNAs) in organisms was first realized in 1993. DNA microarrays, which allow the simultaneous interrogation of many DNA/cDNA loci by nucleic acid hybridization, became a reality in 1996. Remarkably the draft human genome sequence was released in 2001 and completed in 2003. Massively parallel sequencing became an accessible laboratory tool from 2005, and genomic scale analysis has become possible in diagnostic laboratories.

In brief, the explosive accumulation of genetic knowledge has translated into escalating clinical demands for molecular diagnostics in clinical laboratories. Consequently, An understanding of the fundamental aspects of molecular biology, as outlined in this chapter, is required for the effective implementation and interpretation of molecular diagnostics. In addition, the readers should note that discussions in this chapter refer primarily to **eukaryotes** (such as humans whose cells have a true nucleus bounded by a nuclear membrane) and not to **prokaryotes** (such as bacteria whose cells do not).

The Essentials

On the simplest level, genes are defined as segments of DNA that encode for proteins or **ribonucleic acid (RNA)** products with biological functions. DNA is a biological substance that carries genetic information and is a polymer of **nucleotides** or bases. Genetic information is reproduced from parent to daughter cells during cell division through the process of DNA **replication**. When genes are expressed ("switched on"), the DNA sequence is transcribed into RNA. RNA molecules are polymers of ribonucleotides that exist in a number of functional forms. RNA molecules that act as intermediates for protein production are termed messenger RNA (mRNA). RNA molecules that serve a direct biological function without coding for a protein are collectively termed ncRNAs.[13] mRNA is the product of a transcribed nucleotide sequence and is in turn translated into a protein, which is a polymer of amino acids. Each amino acid is encoded by a triplet nucleotide code, termed a **codon**. The human **genetic code** comprises 64 codons encoding for 21 amino acids and 3 stop codons. mRNA codons are read by the anticodon regions of transfer RNA (tRNA) molecules, which are small RNAs that bring the corresponding amino acid to the growing polypeptide chain. The polypeptide chain is synthesized by **ribosomes**, which are macromolecular complexes containing ribosomal RNA (rRNA) and a protein component with catalytic function.

Most human cells contain two full copies/versions of the haploid human genome, which is organized and packaged into 23 pairs of chromosomes (diploid genome). A chromosome is a highly ordered structure of a single DNA molecule with specialized structural features, namely, one **centromere** and two **telomeres**. Every individual inherits one copy/version of the human genome from his or her father and another from the mother. Thus, the human genome contains two copies, termed alleles, of each autosomal gene. Although a gene sequence may encode for a specific protein or RNA with defined functions, alleles of genes may demonstrate sequence variations that in turn contribute to variations in the functional characteristics of the gene product between individuals. The primary nucleotide sequences of the two gene alleles form the **genotype**, whereas the expressed function or biological effect of the gene product is termed the **phenotype**. Thus one could study a human disease or trait at the genetic level through determination of the allelic sequence of a gene by genotyping or at the functional level by phenotyping. Examples of phenotyping include the investigation of (1) enzyme concentrations or activities, (2) ABO blood groups, (3) electrophoretic mobility of hemoglobin variants, (4) RNA expression levels, and (5) others. The choice of genotyping or phenotyping for making a diagnosis depends on the specific diagnostic application and the strength of the association between a genotype and its consequential phenotype.

Nucleic Acid Structure and Organization

An intimate relationship has been observed between nucleic acid structure and function. The physiological function of nucleic acid is facilitated by its structure. Although an alteration in the structure of nucleic acids would lead to an altered function, an altered function, on the other hand, may be seen as an altered structure. Thus, a discussion of nucleic acid structure is pertinent to further discussion on nucleic acid function.

Molecular Compositions and Structures of DNA and RNA

DNA

The physicochemical properties and functions of nucleic acids are largely governed by the compositions and structures of DNA and RNA. A single molecule of DNA is a polymer consisting of a backbone of invariant composition and side groups arranged in a variable sequence (Figures 47-1 and 47-2). The polymer is synthesized from monomers (nucleotides) composed of the sugar deoxyribose, a phosphate residue, and a **purine** or **pyrimidine** base. The purines are adenine (A) and guanine (G), and the pyrimidines are cytosine (C) and thymine (T) (see Figure 47-1). The four nucleotide building blocks of DNA are (1) deoxyadenosine triphosphate (dATP), (2) deoxyguanosine triphosphate (dGTP), (3) deoxycytidine triphosphate (dCTP), and (4) deoxythymidine triphosphate (dTTP). Nucleotides are joined by phosphodiester bonds that link the 5′-phosphate group of one to the 3′-hydroxyl group of the next (see Figure 47-2). No 3′-3′ or 5′-5′ linkages are present; thus the sugar and phosphate moieties compose the nonspecific portions of the molecule. The sequence of the bases

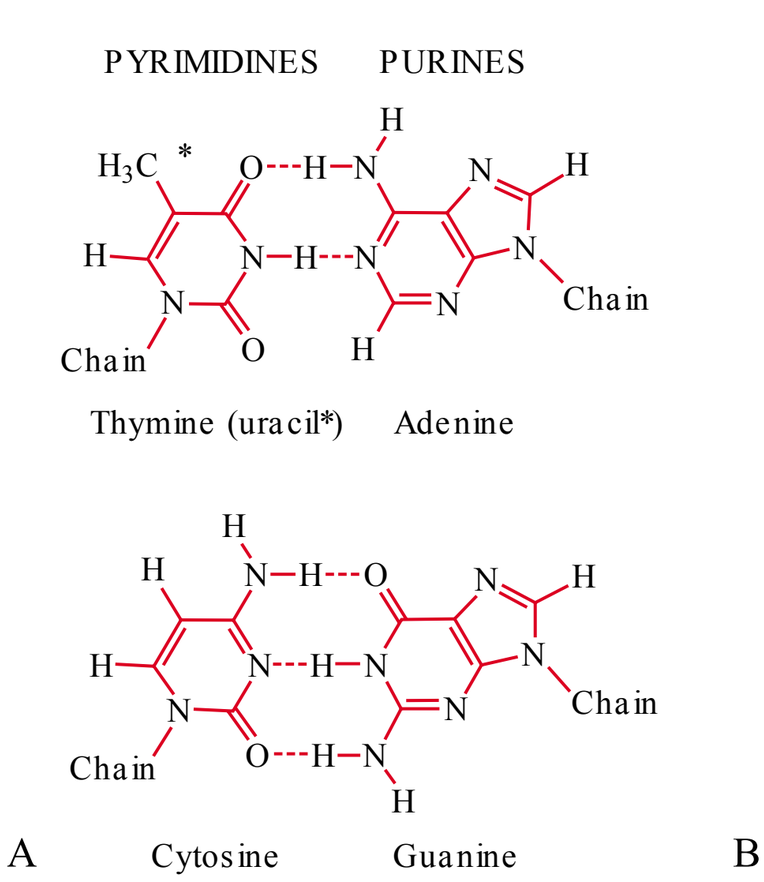

Figure 47-1 A, Purine and pyrimidine bases and the formation of complementary base pairs. Dashed lines indicate hydrogen bonds. (In RNA, thymine is replaced by uracil, which differs from thymine only in its lack of the methyl group.) B, A single-stranded DNA chain. Repeating nucleotide units are linked by phosphodiester bonds that join the 5′ carbon of one sugar to the 3′ carbon of the next. Each nucleotide monomer consists of a sugar moiety, a phosphate residue, and a base. (In RNA, the sugar is ribose, which adds a 2′-hydroxyl to deoxyribose.) (Modifed *f*rom Piper MA, Unger ER. Nucleic acid probes: a primer *f*or pathologists. Chicago, IL: ASCP Press, 1989.)

varies from molecule to molecule and uniquely identifies each DNA polymer, which, as discussed later, determines the identity and function of the protein or RNA products that the DNA encodes.

Although the purines and pyrimidines are of different compositions and sizes, when in the proper orientation, adenine forms two hydrogen bonds with thymine, and guanine forms three hydrogen bonds with cytosine, to form planar structures of similar dimensions (see Figure 47-1). T is combined with the fact that the base portion of each nucleotide is hydrophobic contributes to the energetically favorable secondary structure of DNA as it is found in its native form a right-handed, double-stranded helix. T e planar base pairs stack in the inside of the helix, ten bases per turn, whereas the hydrophilic sugar-phosphate backbone forms noncovalent bonds with surrounding water molecules. For the two DNA polymers to form the proper hydrogen bonds between the bases, two requirements must be fulfilled: the polymers must run in opposite directions (antiparallel) as defined by the free hydroxyl groups at each end (3′-5′ vs. 5′-3′), and the sequences of each molecule must be such that A:T and G:C hydrogen bonds are always formed (base pairing). Two DNA strands that meet this requirement are called complementary.

Owing to base pairing and the double-helical conformation, double-stranded DNA (ds-DNA) is an exceptionally stable molecule. Retention of **base pairs** in the inner portion of the helix prevents disruption by water molecules. T e helical conformation places each monomer in an identical orientation within the molecule and forms the same secondary bonds as every other monomer. T is secondary bonding contributes to the overall stability. Because the base pairs are of similar size, the helix retains a constant angle of rotation and avoids distortion. All of these features dictate that all ds-DNA molecules, regardless of base sequence, retain the same shape and size within a pH range of approximately 4 to 9. Outside these limits, the base pair bonds are disrupted and the helix unwinds.

RNA

RNA is chemically very similar to DNA but differs in important ways. For example, the sugar unit is ribose with an added hydroxyl group at the 2′ position, and the methylated pyrimidine uracil (U) replaces thymine. RNA exists in various functional forms but mostly as a single-stranded polymer that is much shorter than DNA and that has an irregular three-dimensional structure. Despite their irregular shape, RNA conformations are not random structures, and the folding mechanism of RNA molecules is complex. T e secondary structure adopted by an RNA molecule is to a large extent related to its nucleotide sequence. RNA molecules fold sequentially from 5′ to 3′ to form stable submotifs dictated by their primary sequence. One such example is the hairpin loop structure of precursor **microRNAs (miRNAs)** (see later section on ncRNAs). RNA molecules may adopt further tertiary folding. An RNA molecule has the potential to be folded into a number of different conformations, but usually only one conformation is functional. T e folding process is influenced by (1) ions, (2) cofactors, and (3) proteins. Once an RNA molecule adopts a conformation most favored by its immediate cellular environment, it rarely switches to another conformation. RNA molecules also will further interact with other RNA or protein molecules to form complex quaternary structures, such as ribonucleoproteins, that are essential to certain cellular processes.

Chromosome Structure

DNA molecules are extremely long and in the eukaryotic cell are maintained in orderly and compact three-dimensional structures. Each diploid human cell contains two full sets of the human genome with each copy consisting of approximately 3.2 billion nucleotides. T is vast amount of genetic material is organized into 23 homologous chromosome pairs with each pair contributed by a homolog of maternal origin and one of paternal origin. T e two chromosomes of each pair are similar (homologous) and, except for the sex chromosomes (X and Y),

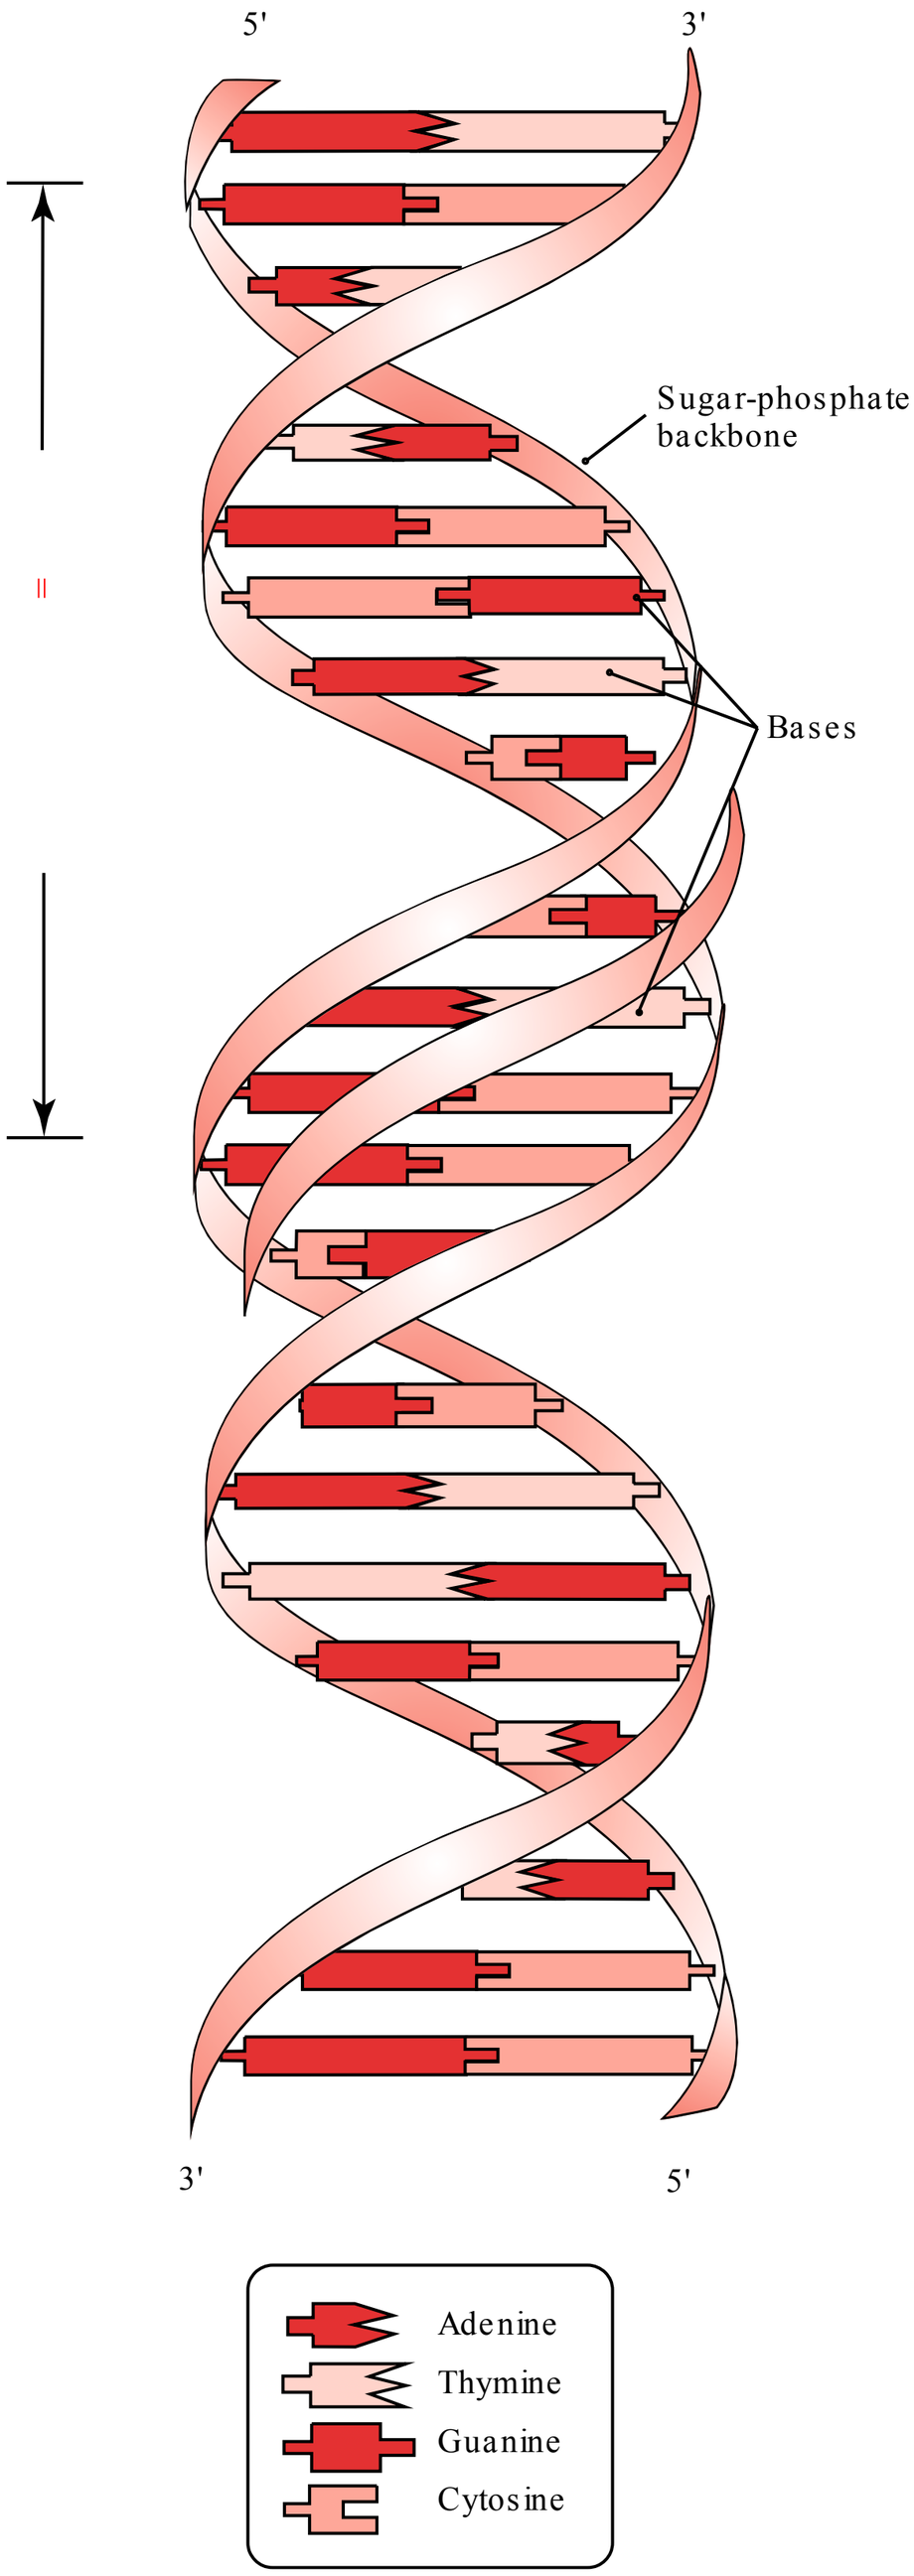

Figure 47-2 The DNA double helix with sugar-phosphate backbone and pairing of the bases in the core-forming planar structures.

contain the same genes arranged in the same sequence. Each chromosome is a highly ordered structure of a single ds-DNA molecule, compacted many times with the aid of structural **DNA-binding proteins** such as **histones** (Figure 47-3). The chromosomes are in their most compact state and appear as finger-like structures during metaphase of the cell cycle. A primary constriction, the centromere, is also notable on each chromosome. The ends of the chromosomes are termed the telomeres (see Figure 47-3). Both centromeres and telomeres have specialized functions, which are discussed later. The non-sex chromosomes, the **autosomes**, in the human genome are numbered in order of decreasing size (except chromosomes 21 and 22). Chromosome 1 contains 250 million base-pairs (megabase pairs or Mbp), and chromosome 21 is 48 Mbp long. The chromosomal arrangement of human DNA not only allows packaging of the vast human genome into the limited physical dimensions of the cell nucleus, but also governs one of the Mendelian laws of inheritance on independent assortment whereby genes located on different chromosomes recombine at random from one generation to the next.

Chromatin Packing

Nuclear DNA in conjunction with its associated structural proteins, including histone and nonhistone proteins, is known as **chromatin**. Chromatin is arranged and organized in a hierarchical fashion whereby the degree of packing or condensation increases with higher levels of structural organization. The **nucleosome** represents the most basic level of chromatin organization and is present as repeated units along the full length of each chromosome. Each nucleosome unit consists of a nucleosome core particle and 20 to 80 base pairs of linker DNA, which spans between adjacent nucleosomes, resembling what has been referred as "beads on a string" (Figure 47-4). A nucleosome core particle involves 146 base pairs of ds-DNA tightly wound 1.65 times around an octamer of histone proteins, two each of four histone proteins, namely, H2A, H2B, H3, and H4. Amino termini or "tails" of these histone molecules protrude from the nucleosomal core. The histone tails are subjected to covalent modifications, including (1) acetylation, (2) methylation, (3) phosphorylation, and (4) ubiquitination (a process that features the attachment of ubiquitin a small regulatory protein).[7] The linker DNA segments are associated with the linker histone H1. Nucleosomes are further packed in successive levels of complexity by up to a factor of 10,000[3]; in the most compact stage, chromatin appears as discrete mitotic chromosomes seen in the metaphase of a cell cycle, as described earlier. The orderly process of chromatin condensation involves **DNA methylation**, histone modifications, ncRNAs, and sequence-specific **DNA-binding proteins**.

Chromatin packing serves the function of containing the genome within the nucleus, but this could potentially render the genetic code inaccessible to various cellular machineries.[3] However, this does not occur because chromatin condensation is not a static process but a dynamic one that changes in a coordinated fashion during the cell cycle. In general, chromatin is much less condensed during **interphase**, at which time DNA is replicated. The extent of chromatin condensation during

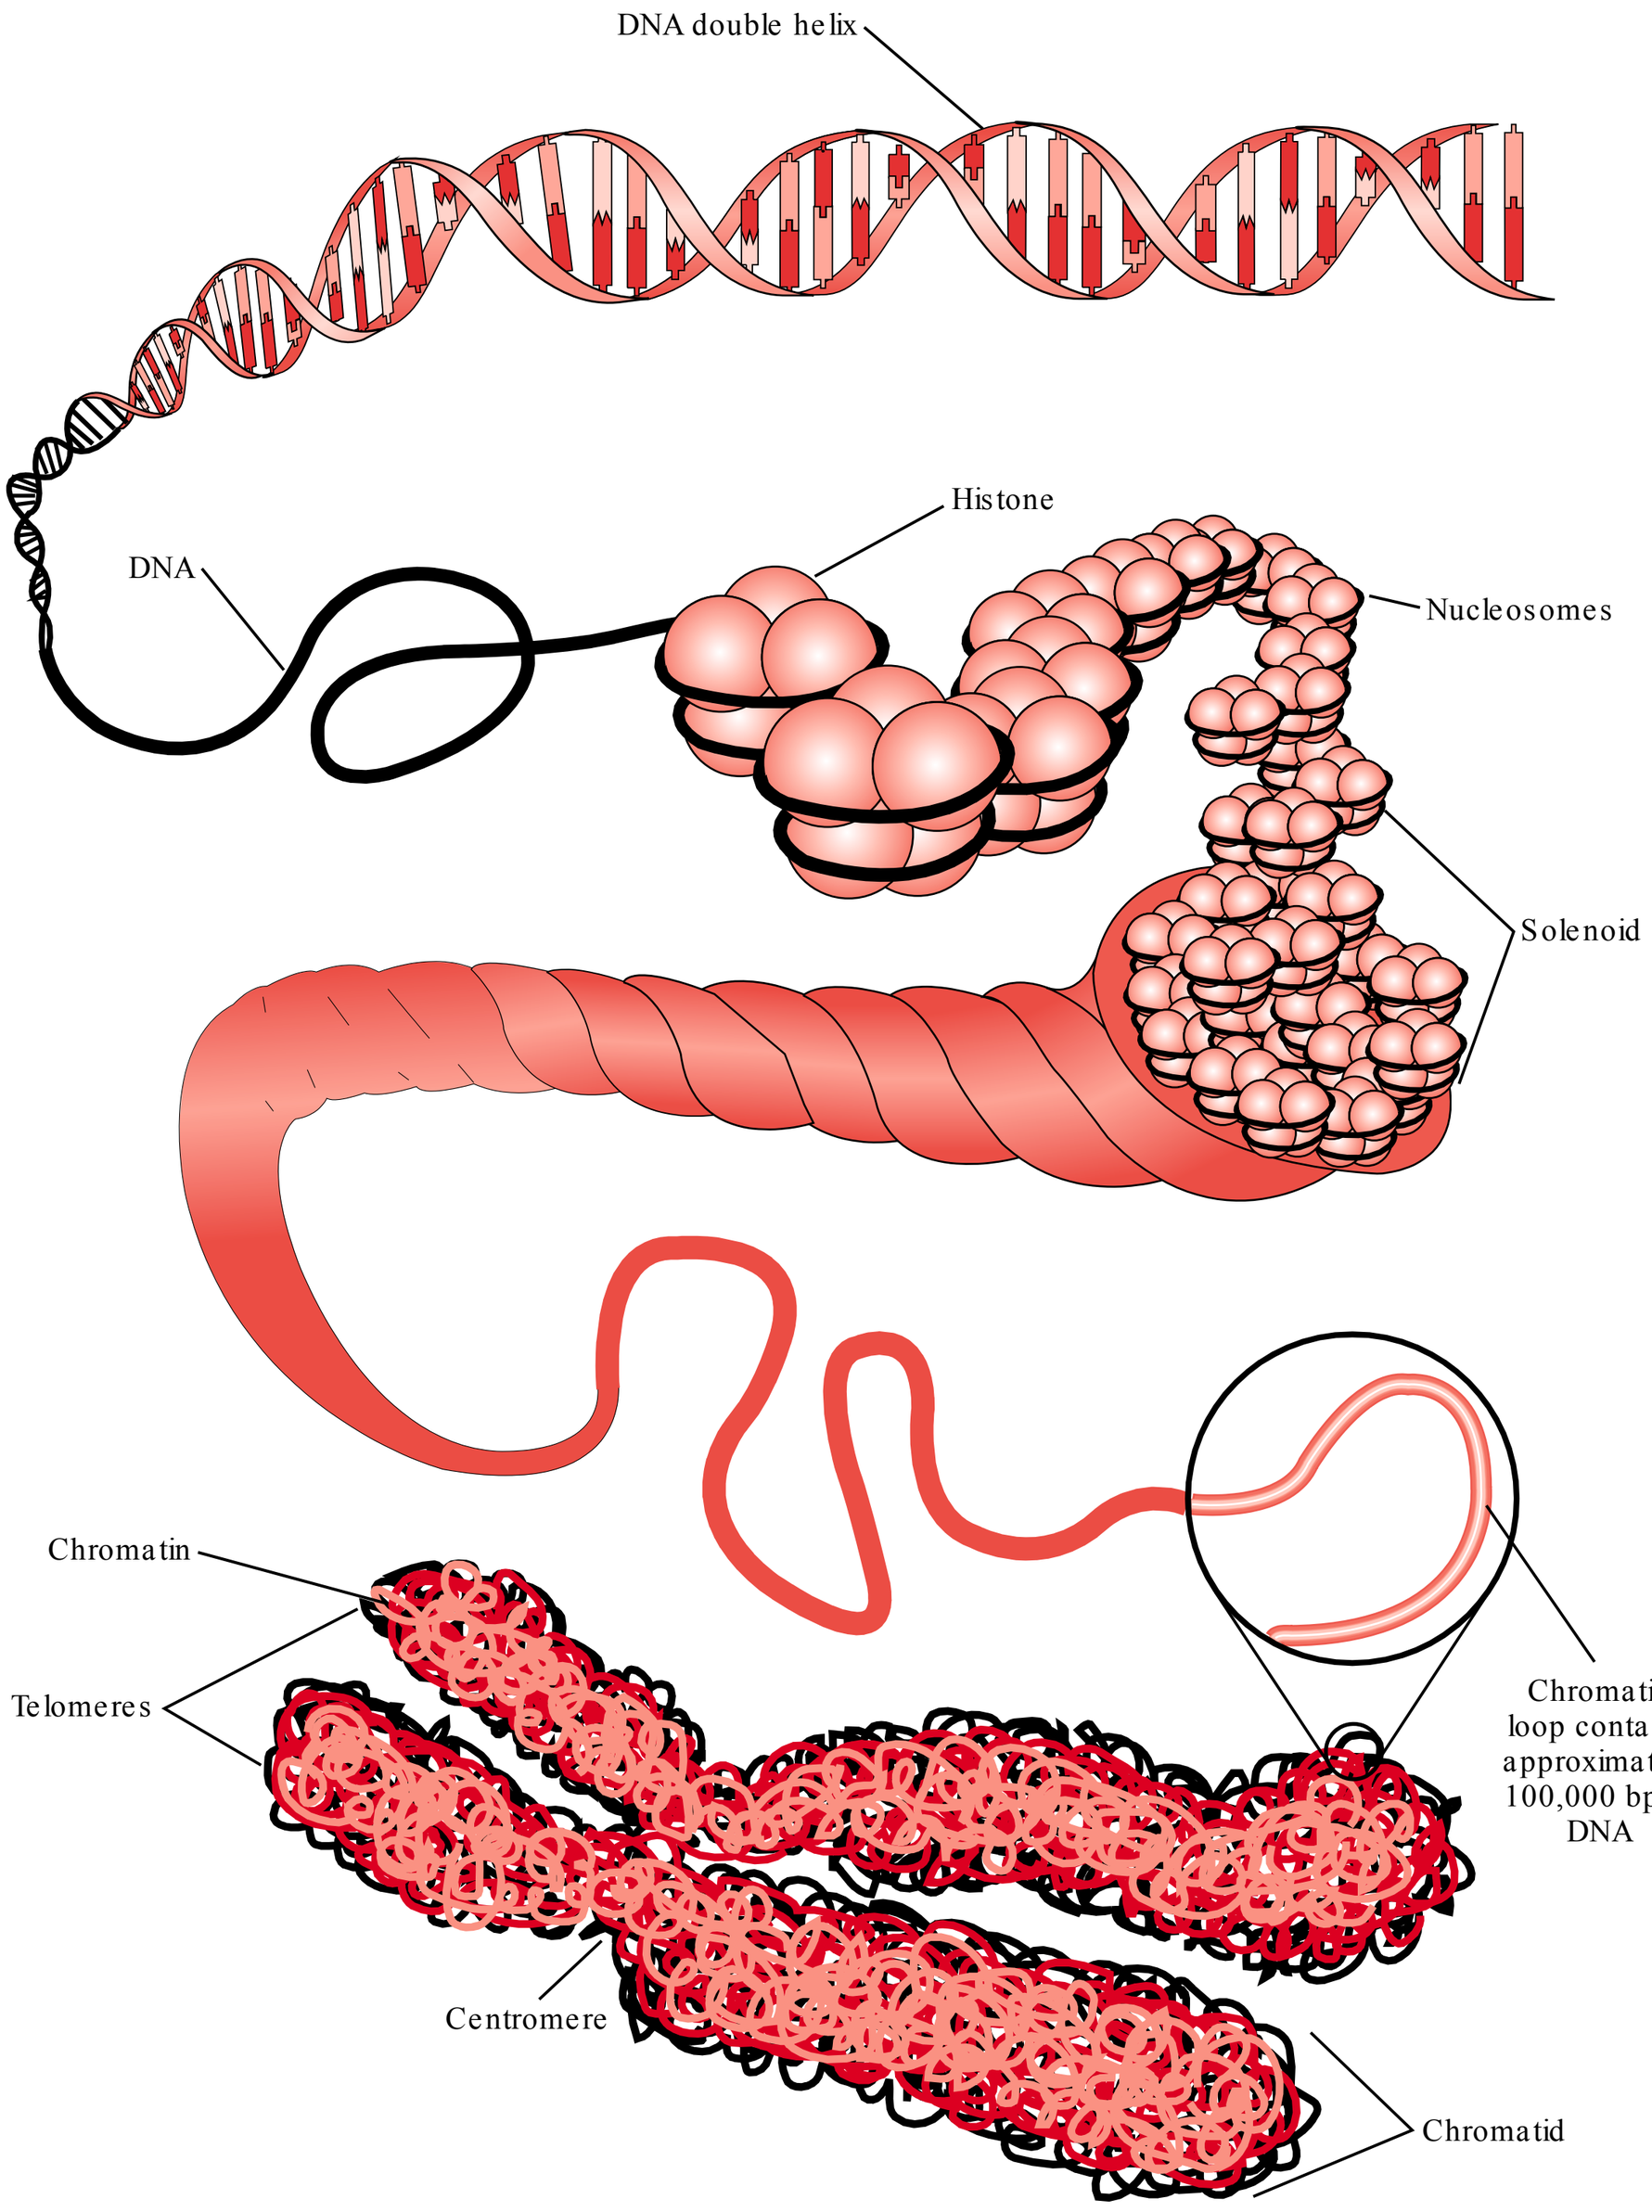

Figure 47-3 Structural organization of human chromosomal DNA. Double-stranded DNA (dsDNA) is wound around histones to form nucleosomes. Nuclear DNA in conjunction with its associated structural proteins is known as chromatin. Chromatin in its most compact state forms chromosomes. The primary constriction of a chromosome is the centromere, and the chromosome's ends are the telomeres.

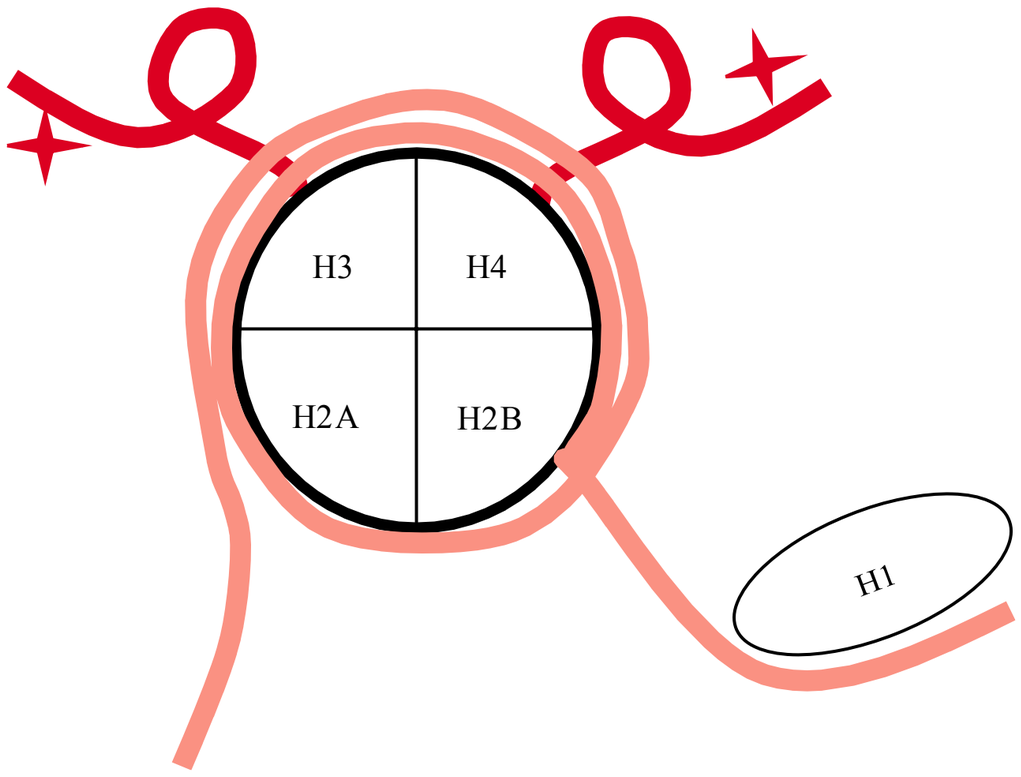

Figure 47-4 Schematic illustration of a nucleosome unit. A segment of DNA is wound around a nucleosome core particle consisting of an octamer with two of each of the histone proteins H2A, H2B, H3, and H4. Tails with modifcations (indicated by a red star) are shown to protrude from H3 and H4. Adjacent nucleosomes are separated by a segment of linker DNA and the linker histone, H1.

interphase varies among regions of the genome. Genomic regions that are rich in genes generally open up to become less compactly organized during interphase and are termed **euchromatin.** Regions that are gene-poor or that span transcriptionally silent genes remain mostly densely packed and are called **heterochromatin**. T is material is important for (1) maintenance of specialized chromatin structures, (2) inactivation of the X chromosome in females, and (3) maintenance of genome stability by stabilizing repetitive DNA sequences.[2] Eukaryote chromosomes contain two specialized regions of heterochromatin, namely, centromeres and telomeres. Centromeres play an important role in directing the movement of chromosomes between daughter cells during cell division. Poor execution of this process could result in incorrect segregation of chromosomes, leading to chromosomal gains or losses in the daughter cells. Telomeres contain repetitive nucleotide sequences that are located on and protect the ends of chromosomes. Alterations in the lengths of telomeres contribute to aging and cancer development. Genomic regions that remain condensed during the cell cycle such as (1) centromeres, (2) telomeres, and (3) the inactivated X chromosome in female cells are termed constitutive heterochromatin. Also, some other heterochromatin domains are scattered throughout the genome and are able to respond dynamically in various cellular states. T ose regions are termed *f*acultative heterochromatin and are associated with regulation of gene expression.[2] Functional implications of the structural organization of chromatin will be discussed further in the following sections.

Nucleic Acid Physiology and Functional Regulation

Nucleic acids form the repository for hereditary information and provide the means of translating that information into the cellular machinery of life. **Gene expression** refers to the process of transforming the genetic blueprint into functional products that participate in various biological processes of a cell. Faithful reproduction of the DNA content from parent to daughter cells during cell division is termed replication. A gene is expressed through **transcription** of its DNA sequence into RNA. mRNAs encode for proteins, and a polypeptide is synthesized through **translation** of the mRNA base sequence into the corresponding amino acid sequence.

Replication

Each time a cell divides, the entire DNA content of that cell must be faithfully duplicated so that the total complement of hereditary information (the human genome) is retained in each daughter cell. T is process is called replication. Owing to the laws of base pairing that mandates that adenine pairs only with thymine, and guanine only with cytosine, the sequence of a single strand of DNA dictates the sequence of its complementary strand. In replication, each of the two parent strands of a ds-DNA molecule serves as the template for the synthesis of a daughter strand (Figure 47-5). T e process is called semiconservative, because each of the duplicated dsDNA molecules produced in this manner is composed of one parent (conserved) strand and one daughter strand. For replication to occur, the original double-stranded helix must be separated. T is is an energetically unfavorable event that is accomplished with a combination of DNA-specific proteins and enzymes, and synthesis of both daughter strands proceeds as the parent strands separate. Replication is initiated at multiple sites (origins of replication) during this process, but each origin of replication is used only once during a single cell cycle.

Daughter strands are synthesized by DNA polymerase III, an enzyme that reads the parent template and attaches nucleotides to the growing daughter strand according to the base pairing rules of ds-DNA. DNA **polymerase** III begins synthesis at the replication fork (see Figure 47-5), the point of strand separation, with a short RNA primer that base pairs to the parent

template. Later, this primer is excised and replaced with DNA by the DNA repair enzyme, DNA polymerase I. Because DNA polymerase episilon synthesizes DNA only in the 5′-3′ direction, one daughter strand, the leading strand, is synthesized continuously, whereas the other, the lagging strand known as an **Okazaki fragment**, must be synthesized discontinuously in short segments (see Figure 47-5). Fragments on the discontinuous strand are then joined by the DNA ligase enzyme. Many other proteins are involved (1) in unwinding and stabilizing the parent strands for synthesis, (2) in protecting single-stranded regions, (3) in recognizing initiation sites, and (4) in synthesizing the RNA primer. In addition to synthetic capabilities, the DNA polymerases possess an **exonuclease** or "proofreading" function: when an incorrect nucleotide is added to the growing polymer, a conformational change brings the chain in contact with the exonuclease portion of the enzyme, which cuts out ("excises") the incorrect nucleotide. T is helps maintain the integrity of the original DNA sequence, and it has been estimated that one nucleotide error could occur for every 10^5 nucleotides incorporated into the growing strand. However, the proofreading function of DNA polymerase works in concert with a set of DNA repair mechanisms that detect and correct DNA replication errors in such a way that the resultant error rate of DNA replication is reduced to one error per 10^9 to 10^{10} nucleotides replicated. Given that 3 billion base pairs are present in the human genome, about 0.3 to 3 errors occur per cell division.

Transcription

DNA carries information that specifies the production of RNA molecules and proteins that can execute biological functions. T e segment of the genome that specifies the production of a functional product, such as a protein or ncRNA, is termed a gene. In short, a gene is a functional unit of the genome. On the most basic level, the span of a gene encompasses the nucleotide sequence that specifies its ncRNA product or the amino acid sequence of its protein product. However, a series of processes determines the timing and rate of expression of each gene. T ose processes that control gene expression act via regulatory regions of the genome. T us, it is customary to define a gene to be inclusive of such associated regulatory elements. An important regulatory region is the **promoter** of a gene, which, as will be discussed later, is the genomic region where regulatory factors act in concert to activate expression of that gene. Previously, it was generally thought that the promoter region was located immediately 5′ to the start of the protein-coding portion of a gene. Yet, recent evidence demonstrates that regions showing properties of a promoter could be found within the protein-coding portion of genes, toward the 3′ end, or lying at a substantial distance between coding sequences. In addition, the same promoter region could trigger the expression of different DNA segments both 5′ or 3′ to it. Hence, it has become increasingly dif cult to precisely define the physical boundaries of individual genes.

When a gene is expressed, the DNA sequence is first transcribed into RNA. T e process of transferring the sequence information from DNA to RNA is called transcription. Regulation of transcription is the primary mechanism that cells use to control gene expression. Similar to replication, transcription requires separation of duplex DNA strands and uses a polymerase to copy the template DNA strand. For transcription, the polymerase is RNA polymerase II, which first binds to specific sequences in the promoter, called the core promoter, upon initiation of gene expression. Core promoters that have been identified to date generally occur within a hundred bases around the initiation site of transcription, known as the transcription start site, where the first ribonucleotide unit is paired with the template DNA (uracil pairs with adenine). Several nucleotide sequence motifs or patterns have now been recognized among core promoters. For example, one of the best studied core promoter motifs, the TATA box, refers to a short stretch of nucleotides rich in thymine and adenine in repeating patterns. It is typically located about 25 nucleotides "upstream" at the 5′ end of the transcription start site. Some other core promoter elements are located just downstream to the transcription start site. Research has suggested that the various core promoter elements may have different strength and ef ciency in activating gene expression.

To initiate transcription, a series of protein cofactors, known as general transcription *f*actors, is required to bind to RNA polymerase II to form an assembly known as the preinitiation complex, which, in turn, acts on the gene by interacting with the core promoter. Other regions of DNA known as activators or co-activators may interact with the preinitiation complex to stimulate or repress transcription.

Once transcription is activated, RNA polymerase II moves along and unwinds the DNA double helix. T e growing RNA transcript pairs with one of the DNA strands, called the template, where RNA polymerase II adds complementary ribonucleotide triphosphates in a 5′ to 3′ direction. It is now known that both DNA strands of the double helix can act as a template for RNA transcription. For example, when the growing RNA transcript pairs with the antisense (−) DNA strand, the resultant RNA molecule is a copy of the sense (+) strand of DNA, and vice versa. Natural antisense transcripts such as RNA transcripts that are copies of the antisense DNA strand have been better known only in recent years. Both protein-coding and non–protein-coding RNAs have been reported to be natural antisense RNAs.

RNA elongation continues until chain termination occurs. T e precise signaling mechanism for chain termination still is not well understood. T e RNA transcript quickly detaches from the template DNA because restoration of the DNA-DNA duplex is energetically more favorable than is retention of the DNA-RNA hybrid or a segment of single-stranded DNA. T e newly synthesized RNA molecule then undergoes further modification depending on its functional class. We shall discuss the fate of the ncRNAs in a later section of this chapter. Here we focus on describing subsequent processing of the protein-coding RNAs, which are referred to as mRNA. First, the 5′ end of the RNA molecule is modified by the addition of 7-methylguanosine residues to form a structure called a cap (Figure 47-6). T e 3′ end is modified by the addition of multiple adenine bases, called the poly(A) tail (see Figure 47-6). Both the

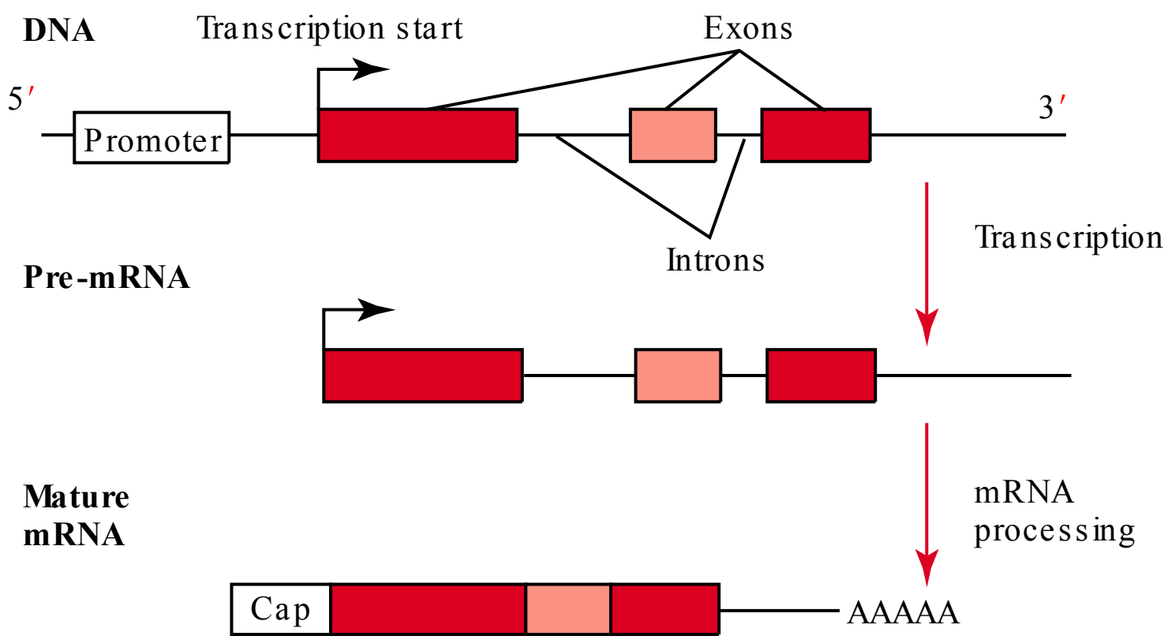

Figure 47-6 DNA transcription and mRNA processing. A gene that encodes for a protein contains a promoter region with variable numbers of introns and exons. Transcription commences at the transcription start site. Pre-mRNA is processed by capping, polyadenylation, and intron splicing and becomes a mature messenger RNA (mRNA).

cap and the tail are necessary for translation of mRNA into protein, and they protect the mRNA molecule from degradation by exonucleases. The coding region of a gene that contributes to the amino acid sequence of the protein is termed an **exon**. Interspersed between exons are noncoding regions termed **introns** (see Figure 47-6). The number and size of introns and exons differ among genes. Excision or splicing of the noncoding introns is carried out by a molecular complex termed a **spliceosome**. These complexes are composed of multiple small nuclear ribonucleoprotein particles. Spliceosomes mediate the cleavage and ligation of RNA at specific recognition sequences, termed splicing donor and acceptor sequences. After the introns have been removed, the exons are juxtaposed to each other, forming a mature mRNA molecule (see Figure 47-6) that is transported into the cytoplasm, where protein translation takes place.

Translation

Translation is the process whereby the mRNA sequence directs the amino acid sequence during protein synthesis. To date, 22 amino acids have been reported in nature. Each amino acid is specified by a three-nucleotide sequence known as a codon. Because 64 possible codons are known, most amino acids are specified by more than one codon. One codon, UAA, does not code for amino acids but always signals termination of protein synthesis (a stop codon). UGA codes for a stop or for selenocysteine, and UAG codes for a stop or for pyrrolysine, depending on adjacent sequences or RNA-binding proteins. With the exception of pyrrolysine, which is the most recently identified amino acid and so far has been found in proteins of bacteria and archaea only, all other amino acids are involved in human protein synthesis. The full menu of codon sequences forms the genetic code, which is shown in Table 47-1.

Translation takes place on ribosomes, which are ribonucleoprotein complexes that function as protein synthesis factories. A ribosome binds to the initiation site on mRNA to form an initiation complex. Protein synthesis begins at the translation initiation codon, AUG, which codes for the amino acid, methionine. The region of the mRNA molecule preceding the

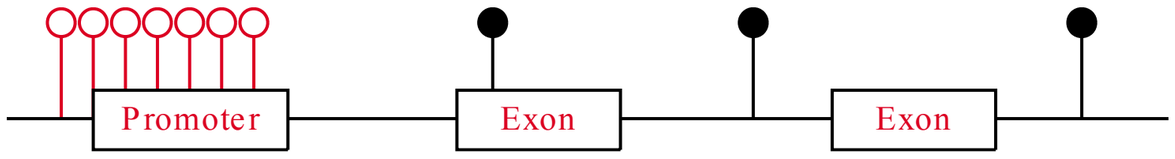

Figure 47-7 Normal DNA methylation pattern in the human genome. Sites of CpG dinucleotides are indicated by circles. CpG islands in association with gene promoters are generally unmethylated, but isolated CpG dinucleotides are methylated. Filled circles, methylated; open circles, unmethylated.

initiation codon is termed the 5′ untranslated region (5′UTR). The initiation codon and each subsequent codon are "read" by tRNA, short RNA molecules that have a sequence complementary to an amino acid codon (anticodon) and are bound to the amino acid molecule specified by the codon. As synthesis proceeds, the appropriate tRNA anticodon forms base pairs with the next mRNA codon and thus brings this amino acid bound to it into close proximity of the growing peptide chain. An enzyme on the ribosome then catalyzes the formation of a peptide bond between the amino acid and the growing peptide chain. The previous tRNA is released and the appropriate tRNA (with its amino acid) is attached to the next codon. The ribosome moves along the mRNA until a stop codon is reached and synthesis is complete. The ribosome and the protein product are then dissociated from the mRNA. More than one ribosome can move along an mRNA molecule at a time, forming a polyribosome. The rest of the mRNA molecule downstream to the stop codon is termed the 3′ untranslated region (3′UTR).

Genetics and Epigenetics

Genetic and **epigenetic** phenomena are intimately related and work in concert to bring about the normal development and functioning of each cell and the whole organism. In general, genetic events are related to the sequence information of DNA, and include the consequences of transmission of a particular DNA sequence (e.g., inheritance of DNA mutations or polymorphisms) or of acquisition of DNA sequence variations (e.g., accumulation of somatic mutations in aging or cancer development). These pathologies are discussed in Chapter 49. On the other hand, a broad definition of epigenetics encompasses processes that alter gene function or its interpretation by mechanisms other than those that rely on DNA sequence change. Practically, epigenetics has evolved to include the study of (1) DNA methylation, (2) genomic imprinting, (3) histone modifications, (4) chromatin remodeling, (5) ncRNA regulation, and (6) other processes. Most of these processes add another dimension to gene expression control and thus play a role in all fundamental cellular events, including (1) cell differentiation, (2) cell growth, (3) cell death, and (4) DNA repair.

DNA Methylation

DNA methylation is possibly the most widely studied epigenetic phenomenon. It refers to the addition of a methyl group to the fifth carbon position of cytosine residues in CpG dinucleotides. CpG dinucleotides are present throughout the genome and may exist singly as an isolated CpG site or in clusters, termed CpG islands (Figure 47-7). Most CpG dinucleotides in the human genome are methylated; these include CpG sites that are (1) within genes, (2) within intergenic regions, and (3) in DNA repeat elements (see Figure 47-7).[12] Unmethylated regions of the human genome are mostly found at CpG islands located (1) at the 5′ ends, (2) in promoters or first exons of genes, and occasionally (3) in some intergenic (a stretch of DNA sequences located between genes) CpG islands.[12] However, it is noteworthy that not all gene promoters are associated with CpG islands, and not all promoter-associated CpG islands are unmethylated. About 56% of human genes have promoters with CpG islands.[12] Some 10% of promoter CpG islands are methylated.

It has been well accepted that DNA methylation mediates the silencing of gene transcription. The methylation of gene promoters hinders the association of methylation-sensitive transcription factors, thus preventing gene activation. Consequently, the promoters of actively transcribed genes are generally unmethylated, while silenced genes are associated with methylated promoters. Because gene expression varies between cell types, the profile of DNA methylation differs between cell and tissue types. Furthermore, a CpG island may be composed of varying numbers of methylated and unmethylated CpG sites. Hence, a genomic region can be further described in relative degree of methylation using the term hypomethylated or hypermethylated. It has been suggested that stably silenced genes tend to be associated with densely methylated promoters, and hypomethylated gene promoters can potentially be activated.[12] Methylation of the nonpromoter regions of genes, however, is thought to suppress inadvertent transcription.[12] Furthermore, methylation of repeat elements in the genome helps to maintain chromosome stability by preventing translocations and insertions of transposons, which are repeat sequences that could randomly insert into the genome, causing gene disruptions.

Because DNA methylation has implications for gene expression, aberrant changes in DNA methylation profiles may cause pathologies. For example, aberrant hypermethylation of gene promoters, particularly those of tumor suppressor genes, contributes to cancer development. Hence, it is important that the DNA methylation pattern of a cell should be faithfully propagated to its daughter cells upon cell division. This process is executed by maintenance **DNA methyltransferases (DNMT)**. DNMT1 is said to perform a "maintenance" role because the DNA methylation patterns inherited by somatic cells were originally laid down by other de novo DNA methyltransferases (DNMT3a and DNMT3b) in the early embryo.

After embryo fertilization, the genome becomes demethylated (except imprinted loci; see discussion later in this chapter)

to pave the way for the establishment of developmentally related patterns of DNA methylation by de novo DNMTs. Genomic imprinting and gene dosage compensation of X-linked genes in females, termed X-inactivation or lyonization, are also mediated by DNA methylation.

X chromosome inactivation is an epigenetic phenomenon that occurs in female cells. Each female cell has two X chromosomes, and each male cell has only one X chromosome. The function of one of the X chromosomes in female cells is epigenetically silenced, so the dosage of X chromosome genes in female and male cells is the same. Gene silencing on the inactive X chromosome is maintained by dense methylation of CpG island promoters. Within each female cell, either of the X chromosomes could be chosen for inactivation.

Genomic imprinting refers to the phenomenon whereby the function of each of the two alleles of a gene is determined by its parental origin. Differential methylation of the imprinted locus from the time of germ cell development allows recognition of the parental origin of imprinted alleles by cellular processes. The human insulin-like growth factor-2 H19 (IGF2-H19) locus on chromosome 15 is an example of an imprinted locus in which a maternal allele is unmethylated and a paternal allele is methylated. Inheritance of two copies of the paternal or maternal allele (rather than one allele from each parent) is called disomy and results in significantly different clinical outcomes, namely, Prader-Willi and Angelman syndromes, respectively.

Histone Modifications

Hypermethylated CpG dinucleotides are also known to attract the binding of methyl-CpG binding proteins, such as methyl-CpG binding protein 2 (MECP2) and methyl-CpG binding domain proteins (MBD1 and MBD2), which further block the association of a number of transcription factors and thus block transcription.[7] It is now appreciated that these methyl-CpG binding proteins have the ability to recruit histone deacetylases, a phenomenon that leads to deacetylation of histones and ultimately represses transcription.

As discussed, histones are an integral part of nucleosomes, the basic repeating structural unit of chromatin. The amino termini of histone proteins can be modified post-translationally by processes that include (1) acetylation, (2) methylation, (3) phosphorylation, and (4) ubiquitination (see sites of modifications in Figure 47-4).[7] Acetylation of the lysines on amino termini of histones H3 and H4 by histone acetyltransferases decreases histone-DNA interaction and improves accessibility of DNA to transcriptional activation. On the contrary, histone deacetylation by histone deacetylases promotes the formation of compact nucleosomes, leading to repression of transcription. Histone deacetylation is in fact a key component of the assembly of heterochromatin, the transcriptionally inactive chromatin.[2] Methylation of the ninth amino acid residue, lysine, on histone H3 generates a binding site for heterochromatin protein (HP1) and thus is another key event in heterochromatin formation. Phosphorylation of the tenth amino acid, serine, on histone H3 is important for chromosome condensation and mitosis.

Nucleosome Positioning and Remodeling

Besides histone modifications, the position of nucleosomes is known to affect the transcriptional activity of the corresponding region of DNA. It is now known that the positioning of histones is not an entirely random process. It has been demonstrated that nucleosome-free regions are present at the 5′ and 3′ ends of genes. The 5′ nucleosome-free region is thought to be the assembly point of the preinitiation complex for transcription, and the 3′ one is the location of transcription termination.[3] A nucleosome unit is located just upstream to the 5′ nucleosome-free region, and another nucleosome is located just downstream to it, close to the transcription start site. The location of the nucleosome nearest to the transcription start site is predictable and consistent.[3] Positioning of the nucleosomes farther downstream through the gene, however, is more random. In summary, it seems that mechanisms control the positioning of nucleosomes so that their presence will not be inhibitory to the initiation of transcription.

During transcription, the nucleosomes along a gene undergo a series of changes successively. First, histones H2A and H3 are replaced by the histone variants, H2A.Z and H3.3. The histone tails are acetylated and methylated. The nucleosome would then be repositioned laterally and ultimately evicted to clear the DNA for access by the transcription machinery.[3] The nucleosome may then return to the DNA after RNA polymerase II has passed through. Consequently, nucleosomes are dynamic structures that can be remodeled according to the transcriptional demands of the cell.

Noncoding RNAs

It was once thought that much of the transcriptional activity of the human genome was directed toward the production of proteins, but exons of protein-coding genes occupy only 1% to 2% of base pairs in the human genome. Thus, the rest of the genome was previously thought to be "junk" DNA, serving no function, and was merely a fossil of our evolutionary past. The availability of innovative technologies in recent years has enabled researchers to study transcriptional activity or RNA expression on a genome-wide scale.[4] These studies revealed that almost the entire genome is transcribed. Transcription takes place in both sense and antisense directions. The same genomic region could serve as the template for many nonoverlapping or overlapping transcription units. Most transcription units do not result in the production of a protein product. Researchers became aware that some of the transcribed RNA molecules serve a direct biological function. An increasing number of classes of such functional RNA molecules have been described; they are collectively termed ncRNAs.[13] In retrospect, rRNA and tRNA are the earliest classes of ncRNAs described. Most recently, a class of short ncRNAs, miRNAs, has become the focus of much research interest.

MicroRNA

Mature, functional miRNAs are 21 to 24 nucleotides long. The first step in the miRNA biogenesis pathway involves the initial transcription of an RNA molecule in the nucleus by RNA polymerase II. The first transcript, termed the primary miRNA,

may be derived from short introns or a longer primary transcript that subsequently gives rise to multiple mature miRNAs. Regions of the primary miRNA that ultimately contribute to sequences of the mature miRNA are typified by their adoption of a stem-loop, also known as hairpin conf guration, with imperfect base pairing between sequences on both sides of the stem. T e primary miRNA is cleaved by **Drosha**, a Class 2 RNase III enzyme. T e resultant RNA molecule, which is approximately 70 nucleotides long, is termed the precursor miRNA. T e precursor miRNA is exported to the cytoplasm of the cell, where another RNase III–like enzyme, Dicer, cleaves at the loop end of the molecule, thus generating a double-stranded RNA product. T e double-stranded product of Dicer is 21 to 24 nucleotides long, consisting of a mature miRNA paired with its imperfect complementary strand, termed miRNA*. Some evidence suggests that miRNA* may serve some biological function, and the conclusion awaits further investigation.

T e mature miRNA detaches from its partner and is incorporated into the RNA-silencing complex (RISC), which includes one or more **Argonaute proteins** that are responsible for the gene silencing process known as RNA interference (RNAi). T e biological function of miRNA is effected through RISC. T e miRNA pairs with the 3′ untranslated region of mRNAs, leading to (1) repression of protein translation or (2) mRNA degradation. T e actual biological consequence is determined by the degree of complementarity base pairing between the miRNA and the target mRNA. mRNAs that can be influenced by a particular miRNA are referred to as the target mRNAs of the corresponding miRNA. More than 850 human mature miRNAs have now been discovered. Because miRNAs can function via imperfect base pairing to mRNA, each miRNA can have an effect on multiple target mRNAs.

miRNAs modulate gene expression at the post-transcriptional level. T erefore, they are involved in many biological processes, including development and cell differentiation. T ey regulate (1) cell proliferation, (2) apoptosis, and (3) maturation. Because of their important regulatory role, aberrant expression of miRNAs has been reported for a myriad of diseases involving, for example, the (1) cardiovascular, (2) neurologic, (3) musculoskeletal, (4) endocrinologic, and (5) immunologic systems. Moreover, aberrant miRNA expression has been implicated in carcinogenesis. T e association of miRNAs with pathologies, coupled with recognition of the presence of miRNAs in plasma and serum, makes them attractive candidate biomarkers for disease diagnosis and monitoring.

Other Noncoding RNAs

Besides miRNA, several other novel classes of ncRNAs have been discovered. In general, the ncRNA classes are subdivided into short and long ncRNAs based on their nucleotide lengths, using an arbitrary cutoff of 200 bases.[13] T e group of short ncRNAs includes the miRNAs described earlier and several other species. Small interfering RNAs (siRNAs) are 21 to 22 nucleotides long and are produced by Dicer cleavage (an endoribonuclease in the RNase III family) of perfectly complementary double-stranded RNA molecules. siRNAs form complexes with certain Argonaute proteins and are involved in (1) gene regulation, (2) transposon control, and (3) viral defense.[13] Piwi-interacting RNAs (piRNAs) are 26 to 30 nucleotides long and function in the germline to regulate transposon activity and the chromatin state.[13] piRNAs are derived not from Dicer cleavage but from successive Argonaute cleavage of long ncRNAs. Promoter-associated RNAs (PASRs) and transcription initiation RNAs (tiRNAs) are 20 to 200 nucleotides and 18 nucleotides long, respectively.[13] T ey are transcribed from promoters and transcription start sites and may be involved in regulating gene expression.

Long ncRNAs include a broad range of transcripts longer than 200 nucleotides and may be as long as 100 kb.[13] Some of these long ncRNAs could be (1) 5′ capped, (2) 3′ polyadenylated, and (3) spliced like mRNAs. Because this is a heterogeneous group of transcripts, their reported functions are varied and include (1) modulation of chromatin architecture, (2) regulation of gene expression, and (3) others.[13] Long ncRNAs have been shown to regulate expression of protein-coding genes by modulating histone methylation and chromatin accessibility.[13] Long ncRNAs may exert biological effects directly or as an intermediary by acting as the precursor of multiple small ncRNAs. For example, the long ncRNA Xist is a transcript that is expressed exclusively from the inactive X chromosome with a key role in initiating the process of X chromosome inactivation. Xist literally coats the X chromosome that is destined to be inactivated and suppresses transcriptional activity. However, besides acting directly, the corresponding transcript in mice, Xist, has been shown to anneal with its antisense partner, Tsix, another long ncRNA. T e Xist-Tsix duplex is further cleaved by Dicer to produce siRNAs, which, in turn, are involved in epigenetic modifications that maintain gene silencing on the inactive X chromosome.

Beyond the Nuclear Genome

The Mitochondrial Genome

Up to this point, this chapter has focused attention on the nuclear genome, but the mitochondrial genome is also an important genetic component of eukaryotic cells. T e human mitochondrial genome is a circular piece of DNA 16.5 kb in length. **Mitochondrial DNA** is transmitted between generations by maternal inheritance with the mitochondria coming from the oocytes and typically not from sperm. Multiple copies of mitochondrial DNA are present within each mitochondrion, and each cell contains a variable number of mitochondria, depending on the energy requirements of the particular cell type. T us, certain cell types may contain up to several thousand copies of mitochondrial DNA. T is greater abundance, compared with that of nuclear DNA, makes mitochondrial DNA attractive for tests for which sample DNA is limited (e.g., crime scenes, pathogen detection, and paleontology). Mitochondrial DNA is double-stranded for most of its length, except at the replication and transcription control region (the D-loop). Unlike the nuclear genome, the mitochondrial genome is not packaged into nucleosomal units. Instead, it has

a unique structural organization. It codes for (1) 13 polypeptides, all involved in the oxidative phosphorylation pathway; (2) two rRNAs; and (3) all of the 22 tRNAs required for mitochondrial protein synthesis. Several other proteins are also required for normal mitochondrial function and are encoded by nuclear genes.

The mutation rate of mitochondrial DNA is ten to twenty times higher than that of nuclear DNA. This high rate has been viewed as resulting from the poor fidelity of mitochondrial DNA polymerase. Germline mutations in the mitochondrial genome generally lead to neurodegenerative and/or myopathic disease, such as MELAS (myopathy, encephalopathy, lactic acidosis, and strokelike episodes) and **Leber's hereditary optic neuropathy**. Somatic mutations, on the other hand, are associated with aging and cancer development. Consequent to the accumulation of sequence variations, more than one population of mitochondrial DNA sequences may be present in a cell. This state is termed **heteroplasmy** as opposed to **homoplasmy**, in which the cell contains a homogeneous population of mitochondrial genomes. When genetic analysis is performed for mitochondrial DNA, a note of caution is warranted on potential problems related to the presence of nuclear pseudogenes, which are DNA segments in the nuclear genome with significant homology to the mitochondrial genome. The close resemblance of the nuclear and mitochondrial DNA segments may result in false-positive detection of mitochondrial DNA sequences; thus the specificity of PCR systems for mitochondrial DNA detection needs to be carefully evaluated.

Circulating Nucleic Acids

Besides being confined within cellular boundaries, nucleic acid molecules are present in the blood circulation. Cell-free DNA and RNA molecules exist in plasma of healthy humans. DNA, RNA, miRNA, and methylated DNA sequences derived from (1) tumors, (2) the unborn fetus, (3) transplant donors, and (4) traumatized tissues have been found in the plasma of 1) cancer patients, 2) pregnant women, (3) transplant recipients, and (4) patients suffering acute pathologies, respectively. Because cell-free nucleic acid molecules could be sampled simply through collection of a peripheral blood sample, the potential for developing molecular diagnostic applications based on their detection is vast. A number of reviews have been published on this topic.[1, 9, 10]

Understanding Our Genome

Evident from the previous discussions, understanding of the structure and function of the human genome has vastly expanded over the past decade. This is a consequence of the availability of high-throughput technologies that allow scientists to study almost every aspect of the human genome on a genome-wide scale. For example, both sequencing and hybridization techniques that allow the interrogation of nucleic acid pools from the entire genome have been extensively employed in research. In terms of sequencing, the so-called next-generation sequencers decode millions to billions of nucleotide fragments in a massively parallel fashion and are capable of producing giga (10^9) bases of sequence output in a matter of days. Regarding hybridization techniques, high-density microarrays with probes carpeting the entire genome, referred to as **tiling arrays**, are readily available. Both sequencing and hybridization techniques can be coupled with various sample preparation protocols for analysis of pools of DNA, RNA, or complementary DNA (DNA generated by reverse-transcribing RNA) from the entire genome or subsets enriched with (1) exon sequences, (2) transcription factor–binding sites, (3) methylated CpG sites, (4) short RNAs, (5) polyadenylated RNAs, and (6) others. Each of these experiments generates vast quantities of data. Basic management and analysis and further interpretation of such large data sets require the use of high-throughput computing. Hence, the field of bioinformatics has flourished and become an essential and fundamental component of life science research.

The first of the whole-genome-scale projects addressed by humankind was the **Human Genome Project**. It is the biggest biological project completed to date. Apart from its ambitious goal of deciphering the 3 billion base pairs that make up the human genetic code, it also represents a model for the (1) planning, (2) organization, and (3) execution of large-scale biological projects. The first serious discussion of the feasibility of such a project can be traced back to the mid-1980s. It was visionary of early proponents to conceive of the project before the advent of high-throughput sequencing technologies. In fact, the proposal was suggested just years after the invention of DNA sequencing in 1977. Based on technology available at the time, sequencing of the human genome would be a mammoth task, requiring a multinational effort. In 1988, a special committee of the US National Research Council of the US National Academy of Sciences formulated a 15-year human genome project, costing some $200 million a year. A genetic map with one **centiMorgan** (cM) resolution was accomplished in September 1994. A physical map involving 52,000 sequence-tagged sites (STSs) was completed in October 1998. The final journey to completion of this project was marked by a highly publicized race between a publicly funded group of investigators and a private effort. The public effort, undertaken by the International Human Genome Sequencing Consortium, consisted of investigators from twenty centers located in six countries: the (1) United States, (2) United Kingdom, (3) Japan, (4) China, (5) France, and (6) Germany. Completion of a draft sequence was announced on June 26, 2000, and it was published in two landmark papers, one from the public team and one from the private team, in February 2001.[6, 14] The final sequence was accomplished in April 2003 with 99.99% sequencing accuracy.

The Human Genome Project has far reaching implications. Technologically, it accelerated the pace of development of (1) sequencing technologies, (2) computational tools for alignment of stretches of DNA reads, and (3) organization of the data. Biologically, the human race has produced a copy of its genetic code. However, many more questions stem from having the reference human genome sequence. For example, how different is the genome between individuals? With the

reduction in the cost of genome sequencing and a reduction in its technical complexity, sequencing of the genomes of a handful of individuals, including that performed by Watson[15] and Venter,[8] the pioneers of the Human Genome Project, has been completed. Cross-comparisons have been made between the sequences of these genomes.

To enhance understanding of human genomic diversity on a broader scale, two large-scale projects were launched. The first one, the International HapMap Project (http://www.hapmap.ncbi.nlm.nih.gov/; accessed December 26, 2013), was launched to study heritable variations such as (1) polymorphisms, (2) patterns of **linkage disequilibrium**, and (3) haplotypes across the human genome. The HapMap Project primarily focuses on one class of genome variations, namely, single-nucleotide polymorphisms (SNPs). Cataloguing genetic variations between different ethnic populations is useful for understanding the ancestral relationships between those populations. Once identified, a catalog of SNPs is also useful in providing landmarks of genomic locations for identification of disease-causing genes. If a SNP allele is found to be associated with a particular disease, the SNP allele serves as a marker for assessment of an individual's susceptibility (statistical probability) of developing said disease.

The second project, the 1000 Genomes Project (http://www.1000genomes.org/; accessed December 26, 2013), also aims to study genomic diversity and disease-causing genes in humans. The approach is based on whole genome sequencing of 1000 individuals, and the analysis is not limited to SNPs. Most recently, researchers have embarked on another approach to identify disease-causing genes through whole genome sequencing of families. This approach entails the comparison of genomic sequences between affected and unaffected relatives within families known to propagate a hereditary disease under investigation.

After the alphabets of the human genome have been spelled out, another obvious follow-up would be to decode the meaning of the 3 billion nucleotides that are the functional aspects of the human genome). This is led to the launch of the Encyclopedia of DNA Elements (ENCODE) Project (http://www.genome.gov/ENCODE/; accessed December 26, 2013), which aims to identify all functional elements within the human genome. A feasibility study targeting 1% of the human genome has been done. Data from just this 1% of the genome have already led to many surprises that overturned many of our earlier simplistic views of the genome. Just to name a few of these surprises, as discussed earlier, other than the 1% to 2% of the genome that was previously annotated as protein-coding and much of the entire genome is transcribed. Promoters that activate transcription are not limited to the 5′ ends of genes but instead are distributed at various locations of the transcription unit. Transcription takes place on both sense and antisense strands with highly overlapping units. Such new information redefines many previously established concepts including very fundamental ones, for example, what is a gene? Our renewed understanding has brought about our appreciation of the highly sophisticated and complex nature of the workings of the human genome. All this new information is facilitated by the advent of high-throughput technologies, as discussed earlier. Our macroscopic view of some functional aspects of the human genome is now improving. However, a long journey lies ahead before we attain a full understanding of each of the specific cellular and molecular mechanisms. Although our current understanding of the wonders of the genome is very limited, it is hoped that ultimately, humankind will have a better grasp of the causative mechanisms of pathologies to facilitate our efforts in (1) predicting, (2) diagnosing, (3) monitoring, and (4) treating disease.

Other large-scale projects that researchers are currently tackling include the Human Epigenome Project (http:// http://www.epigenome.org/; accessed December 26, 2013), which aims to identify, catalog, and interpret genome-wide DNA methylation patterns of all human genes in all major tissues. This would represent yet another major challenge because only one reference human genome is known and many methylomes are present, given the different DNA methylation profiles between cells. Besides genetic polymorphisms such as SNPs, it is now known that structural variations between individuals are characterized by comparatively large regions of gains and losses in DNA and are known as copy number variations. Hence, a copy number variation project aims to catalog and interpret the functional implications of copy number variations.[11]

In conclusion, it is expected that our understanding of the human genome will continue to expand at an unimaginable rate. This is will continue to drive changes in the way medicine and diagnostics is practiced. An emerging theme shows that each individual is a unique being, and much heterogeneity is seen even within the same disease entity. Thus, it is possible that personalized medicine with individualized therapies will be the standard of the future.

Review Questions

1. What are the four bases found in RNA?
   a. Adenine, cytosine, guanine, thymine
   b. Asparagine, cysteine, glycine, threonine
   c. Adenine, cytosine, guanine, uracil
   d. Adenylate, cytosol, guanidil, uracil
2. DNA polymerase is necessary for
   a. adding new nucleotides to a growing DNA strand.
   b. forming an messenger RNA (mRNA) strand from a DNA strand.
   c. releasing the tension in the double helix as replication progresses.
   d. synthesizing protein from messenger RNA (mRNA).
3. Which is true about RNA splicing?
   a. The RNA is spliced to the growing polypeptide chain.
   b. The exons are snipped out and discarded while the introns are spliced together.
   c. The introns are excised while the exons are spliced together.
   d. The promoter sequence is snipped out and the introns and exons are spliced together.

4. How many total chromosomes are found in a normal human somatic cell?
   a. 22
   b. 23
   c. 44
   d. 46
5. What type of bond connects complementary bases between DNA strands?
   a. Hydrogen
   b. Covalent
   c. Phosphodiester
   d. Van der Waals
6. Euchromatin
   a. maintains specialized chromatin structures.
   b. becomes less compactly organized during interphase of the cell cycle.
   c. contains transcriptionally silent genes and is densely packed.
   d. directs movement of chromosomes between daughter cells.
7. Following the attachment of a number of factors to a strand of DNA, the enzyme required for the actual process of transcription to occur is
   a. RNase.
   b. DNA polymerase
   c. RNA polymerase
   d. transcriptase.
8. A nucleic acid is
   a. a nucleotide.
   b. DNA or RNA.
   c. a base pair.
   d. a trinucleotide sequence.
9. The conversion of messenger RNA (mRNA) nucleotide sequences and their attached amino acids into a peptide is referred to as
   a. replication.
   b. transcription.
   c. conversion.
   d. translation.
10. The "Genetic Code" refers to
    a. the relationship between a trinucleotide sequence of RNA and the corresponding amino acid.
    b. the statement that genes are perpetuated as nucleic acid but function in the form of protein.
    c. the relationship between a nucleotide sequence of DNA and the corresponding sequence of RNA.
    d. the complementary pairing of bases along a double strand of DNA.

CHAPTER 48

Nucleic Acid Techniques and Applications

Carl T. Wittwer, M.D., Ph.D., and Noriko Kusukawa, Ph.D.

Objectives

1. Define the following:
   - Amplicon
   - Amplification
   - Blot
   - Hybridization
   - Label
   - Melting analysis
   - Primer
   - Probe
   - Single-nucleotide variant (SNV)
2. For each of the following nucleic acid enzymes, state the enzyme's action, its physiologic function and biological source, and its use in laboratory applications (if any):
   - Ligase
   - Nuclease
   - Restriction endonuclease
   - Reverse transcriptase
   - Polymerase
3. Compare target amplification, signal amplification, and probe amplification techniques, including what is amplified in each and how each is used in a clinical laboratory.
4. List and describe the steps involved in a polymerase chain reaction (PCR) including enzymes and other components required, what occurs in each step, issues with and controls for contamination and/or inhibition.
5. For each of the following target amplification techniques, state the principle of the amplification, components required, differences from conventional PCR, equilibrium quantification methods, and uses of each technique in a molecular diagnostics laboratory:
   - Allele-specific PCR
   - Asymmetric PCR
   - Digital PCR
   - Ligase chain reaction (LCR)
   - Transcription mediated amplification (TMA)
   - Whole genome/transcriptome amplification
6. For each of the following nucleic acid detection methods, state the principle of the method and what is measured by the method:
   - Fluorometry
   - UV spectrophotometry
7. Describe basic nucleic acid electrophoresis, including separation principles, types and uses of gels, and uses of electrophoresis in the molecular diagnostics laboratory.
8. State the principles of the following techniques and their use in a molecular diagnostics laboratory:
   - Branched-chain signal amplification
   - Conformation-sensitive scanning
   - Dideoxy-termination sequencing for DNA
   - High-throughput sequencing
   - Mass spectrometry
   - Oligo ligation
   - Pyrosequencing
   - Restriction fragment length polymorphism (RFLP)
   - Rolling circle amplification (RCA)
   - Single nucleotide extension (SNE)
   - Southern blotting
9. Discuss the uses of hybridization techniques in the molecular diagnostics laboratory, including the principle of basic hybridization, probes and controls used, microarrays, and quantification methods; state the difference between solid-phase hybridization and solution-phase hybridization assays, and give one example of each.
10. For real-time PCR, state the reason it is considered a hybridization assay; list the components used in a real-time assay, including fluorescent dyes, primers and probes available, detection methods, and quantification of product.
11. Describe high resolution melting curve analysis for genotyping and scanning, including principle of melting, uses in single-nucleotide variant (SNV) genotyping, and for heterozygote variant scanning.
12. Analyze and solve case studies related to nucleic acid techniques used in a molecular diagnostics laboratory.

Key Words and Definitions

Allele-specific PCR A version of polymerase chain reaction (PCR) in which specific alleles or DNA sequence variants are amplified at the same locus.

Amplicon The product of an amplification reaction.

Amplification methods Techniques to amplify the amount of target, signal, or probe so that specific sequences are readily observed.

Antisense RNA (asRNA) A single-stranded RNA that is complementary to a messenger RNA (mRNA) strand transcribed within a cell.

Key Words and Definitions—cont'd

Array An ordered linear, two-dimensional, or three-dimensional arrangement of a multiplicity of discrete objects, such as individual deposits (spots or lines) of DNA or reaction chambers.

Asymmetric PCR A version of PCR that preferentially amplifies one strand of the target DNA.

Base pair A purine/pyrimidine pair linked by hydrogen bonds that connects the complementary strands of DNA or of hybrid molecules joining DNA and RNA. The base pairs are adenine-thymine and guanine-cytosine in DNA, and adenine-uracil and guanine-cytosine in RNA.

Branched-chain signal amplification A molecular probe technique that utilizes branched DNA (bDNA) as a means to amplify the hybridization signal.

Calibration An analytical process to determine the functional relationship between measured values and analytical quantities.

Cloning In biology, cloning is the process of producing similar populations of genetically identical individuals. In molecular diagnostics, cloning is the process used to create copies of DNA fragments (molecular cloning), cells (cell cloning), or organisms.

Comparative genomic hybridization (CGH) A cytogenetic technique in which reference and test DNA are respectively labeled with green- and red-fluorescing fluorochromes. Genetic abnormalities are detected by changes in the green-to-red ratio.

Conformation-sensitive gel electrophoresis (CSGE) A type of electrophoretic mutation scanning in which a segment of DNA is screened for mismatch pairing between normal and mutated base pairs.

Copy number variant (CNV) A segment of DNA in which copy-number differences have been found by comparison of two or more genomes.

Denaturing gradient gel electrophoresis (DGGE) An electrophoretic method for separating DNA fragments according to their mobilities under increasing denaturing conditions (usually increasing formamide or urea concentrations).

Deoxyribonucleic acid (DNA) A nucleic acid that carries the genetic information in the cell. It consists of two long chains of nucleotides twisted into a double helix and joined by hydrogen bonds between the complementary bases adenine and thymine or cytosine and guanine. The sequence of nucleotides determines individual hereditary characteristics.

Deoxyribonucleotide triphosphates (dNDT) The building blocks of DNA (typically dATP, dCTP, dGTP, and dTTP).

Detection methods In molecular diagnostics, these are the techniques used to detect nucleic acid sequences, usually after purification and amplification.

Dideoxy-termination sequencing A method of DNA sequencing based on the selective incorporation of chain-terminating dideoxynucleotides by DNA polymerase during in vitro DNA replication. Also known as Sanger sequencing.

Digital polymerase chain reaction A modification of conventional PCR where the sample is separated into a large number of partitions and the amplification is carried out in each partition individually. Also known as dPCR.

DNA microarray An array of microscopic spots of different DNA molecules attached to a solid surface. Also known as DNA chip or biochip.

Electrophoresis Movement caused by an electrical field, often through a gel matrix. Polyacrylamide and agarose are common matrices used to separate DNA and RNA under an electric field.

Endonuclease An enzyme that hydrolyzes an internal phosphodiester bond, splitting a nucleic acid into two or more parts.

Exome The part of the genome that codes for exons, the sequences that remain in the mature RNA after transcription and removal of introns by RNA splicing. It differs from a transcriptome in that it consists of only DNA that is transcribed into mature RNA, excluding transfer RNA, ribosomal RNA, and other non-coding RNA.

Exonuclease An enzyme that removes terminal nucleotides from a polynucleotide.

Flow cytometry A technique for counting cells suspended in fluid as they flow one at a time past a focus of exciting light.

Fluorescence A physical property of some molecules to emit light at a longer wavelength when excited at a shorter wavelength.

Fluorescence in situ hybridization (FISH) A genetic mapping technique using fluorescent tags for analysis of chromosomal aberrations and genetic abnormalities. Chromosome painting is a form of FISH.

Heteroduplex A DNA duplex with internal mismatches or loops.

Hetero-duplex analysis (HDA) A type of mutation scanning in which a segment of DNA is screened by gel or capillary electrophoresis for mismatch pairing between normal and mutated base pairs.

High-resolution melting analysis An indirect method of observing DNA dissociation by using dyes that fluoresce in the presence of double-stranded DNA but not single-stranded DNA.

Homoduplex A perfectly matched DNA duplex.

Hybridization The annealing or pairing of two DNA strands.

Insertion An extra DNA sequence that is present in one sample compared with a reference sequence.

Intron DNA sequence within a gene that is spliced out during messenger RNA (mRNA) processing.

Label A modification that renders a molecule observable.

Ligases Enzyme that covalently joins two DNA strands.

Ligase chain reaction (LCR) A DNA amplification technique that uses four primers instead of two and uses the ligase to ligate or join two segments of DNA.

Loop-mediated amplification (LAMP) A single tube technique for the amplification of DNA that uses a single-temperature incubation.

Melting curve analysis A direct measurement of double-stranded DNA (dsDNA) dissociation during heating. As the temperature is raised, the double strand dissociates resulting in an increase in the absorbance of the solution containing the DNA.

Melting temperature (T_m) The temperature at which 50% of the DNA strands are in the random coil or single-stranded (ssDNA) state. It depends on the length of the DNA molecule and its specific nucleotide sequence.

Key Words and Definitions—cont'd

Microtiter plate A flat plate containing a two-dimensional array of multiple "wells" used as small reaction chambers. Such plates typically have 6, 24, 96, 384, or even 1536 sample wells arranged in a rectangular array.

Multiplex ligation-dependent probe amplification (MLPA) A variation of PCR that permits multiple targets to be amplified with only a single primer pair.

Northern blot A technique for identifying specific sequences of RNA in which RNA molecules are sequentially (1) separated by electrophoresis, (2) transferred to nitrocellulose, and (3) identified with a suitable probe.

Nuclease An enzyme that degrades nucleic acid.

Nucleic acid A complex compound found in all living cells and viruses, composed of (1) purines, (2) pyrimidines, (3) carbohydrates, and (4) phosphoric acid.

Nucleic acid analogs Compounds that are analogous (structurally similar) to naturally occurring RNA and DNA. They are used in medicine and in molecular biology research.

Oligonucleotide A short single-stranded polymer of nucleic acid.

Oligonucleotide ligation assay (OLA) A technique for determining the presence or absence of a specific nucleotide pair within a target gene, often indicating whether the gene is wild type (normal) or mutant (defective).

Peptide nucleic acid (PNA) An artificially synthesized polymer similar to DNA or RNA. The term is somewhat of a misnomer, because PNA is not an acid.

Plasmid An extrachromosomal self-replicating structure found in bacterial cells that carries genes for a variety of functions not essential for cell growth. Plasmids consist of cyclic double-stranded DNA molecules, replicating independently of the chromosomes and transmitting through successive cell divisions.

Polymerases Enzymes that sequentially adds nucleotides onto a growing polynucleotide, usually requiring a primer and a template.

Polymerase chain reaction (PCR) An in vitro method for exponentially amplifying DNA.

Primer An oligonucleotide that serves to initiate polymerase-catalyzed addition of nucleotides by annealing to a template strand.

Probe A nucleic acid used to identify a target by hybridization.

Pseudogene A genetic element that does not result in a functional gene product, usually because of accumulated mutations.

Pyrosequencing A method of DNA sequencing based on the "sequencing by synthesis" principle that relies on the detection of pyrophosphate (PPi) release on nucleotide incorporation.

Real-time PCR Observation of PCR during amplification at least once each cycle.

Restriction endonuclease An endonuclease, usually from bacteria, that cuts nucleic acid in a sequence-specific manner.

Restriction fragment length polymorphism (RFLP) A genetic polymorphism revealed by changes in the sizes of DNA fragments after restriction enzyme digestion and electrophoresis.

Retrovirus A family of RNA viruses containing a reverse transcriptase enzyme that allows the viruses' genetic information to become part of the genetic information of the host cell upon replication.

Reverse transcriptase A polymerase that catalyzes synthesis of DNA from an RNA template.

Ribonucleic acid (RNA) A polymeric biochemical consisting of a long, usually single-stranded chain of alternating phosphate and ribose units with one of four bases bonded to the ribose; the bases are (1) adenine, (2) guanine, (3) cytosine, and (4) uracil.

Rolling circle amplification (RCA) A probe amplification method where, in the presence of template, a linear probe is ligated to form a circle that is replicated continuously by a polymerase and one or more primers.

Sanger sequencing A method of DNA sequencing based on the selective incorporation of chain-terminating dideoxynucleotides by DNA polymerase during in vitro DNA replication. Also known as dideoxy-termination sequencing.

Sequencing Any method that determines the exact order of bases in a DNA fragment.

Serial invasive signal amplification A signal enhancing technique that combines two invasive signal amplification reactions in series in a single-tube format. The cleaved 5′ arm from the target-specific primary reaction is used to drive a secondary invasive reaction.

Single-base primer extension (SBE) assay An assay performed by annealing a primer to ssDNA immediately adjacent to the single base variant.

Signal amplification Any method that increases the signal resulting from a molecular interaction that does not involve target amplification or probe amplification.

Single-nucleotide variant (SNV) Any change in a nucleic acid that involves only a single nucleotide, including base changes, and single base deletions/ insertions. Now favored over the related term "single nucleotide polymorphism" (SNP) and not limited to variants present at a frequency of >1% as is SNP.

Single-stranded conformational polymorphism (SSCP) A gel electrophoresis technique where single-stranded DNA (ssDNA) segments are identified by their abnormal migration patterns.

Southern blot A method for detecting DNA sequence variants after restriction enzyme digestion and size separation by electrophoresis.

Strand displacement amplification (SDA) An amplification technique that uses two types of primers and DNA polymerase and restriction endonuclease to exponentially produce single-stranded amplicons asynchronously.

Target amplification Any method for increasing the amount of target nucleic acid.

Temperature-gradient gel electrophoresis (TGGE) A form of electrophoresis that uses temperature to denature the sample as it moves across an acrylamide gel.

Template A nucleic acid molecule the sequence of which serves as a pattern to be copied by a polymerase to produce a DNA or RNA with a complementary sequence.

Thermocycler A laboratory apparatus used in the amplification of segments of DNA via the PCR. Often, the device has a thermal block with holes where tubes holding the reaction mixtures are inserted. The cycler then raises and lowers the temperature of the block in discrete, pre-programmed steps.

Thermus aquaticus (Taq) DNA polymerase A thermostable DNA polymerase named after the thermophilic bacterium Thermus aquaticus. It is often abbreviated to "Taq Pol" or "Taq" and is frequently used in PCR.

Key Words and Definitions—cont'd

Transcription mediated amplification (TMA) An amplification method that uses RNA polymerase and reverse transcriptase to produce an RNA amplicon from a target nucleic acid. TMA can use either RNA or single-stranded DNA as a template.

Transcriptome The set of all RNA molecules, including (1) messenger RNA (mRNA), (2) ribosomal RNA (rRNA), (3) transfer RNA (tRNA), and (4) other non-coding RNAs produced in one or a population of cells.

Virtual karyotyping A technique used to analyze a short sequence of DNA from specific loci all over a genome to obtain information that reflects a karyotype.

Whole genome amplification (WGA) A non-specific amplification technique that produces an amplified product that represents the initial starting material (whole genome).

Molecular diagnostics requires techniques to detect sequence variations that are minute changes in complex genomes.[3,12] A multitude of molecular tools have been developed that make such analysis easier. In general, molecular diagnostics typically requires: (1) selection and amplification of the **nucleic acid** of interest, (2) visualization of the amplified nucleic acids, and (3) specific identification and often quantification of individual nucleic acid species. Original research references for many of the techniques described here are available elsewhere.[14]

Nucleic Acid Enzymes

Nucleic acid enzymes are critical tools in molecular diagnostics. Common enzymes that act on nucleic acids include those that synthesize longer polymers and those that degrade nucleic acid into shorter fragments. These enzymes are critical for **deoxyribonucleic acid (DNA)** replication and for transcription and must be present in all cells that replicate. In addition to general-function enzymes, a variety of unique enzymes, found in bacteria and viruses, act on specific nucleic acid sequences. Many of these enzymes have been purified and synthesized in vitro. Some have been "engineered" with alterations that improve their performance or stability. The ability to manipulate nucleic acids in vitro with these enzymes has made modern molecular biology possible. Enzymes are also used extensively in nucleic acid diagnostics, including (1) sample preparation, (2) **probe** labeling, (3) signal generation, and (4) amplification.

Nucleases

Nucleases are enzymes that hydrolyze one or more phosphodiester bonds in nucleic acid polymers. They may cleave nucleotides one at a time from the ends (**exonucleases**), or may act only on internal bonds (**endonucleases**). For example, some probe methods are based on 5′-exonuclease activity that cleaves nucleic acids between two fluorescent **labels**. Nucleases are either DNA or **ribonucleic acid (RNA)** specific and may act on only double- or single-stranded polymers. For example, DNAse I digests double-stranded DNA (dsDNA), and S1 nuclease acts only on single-stranded DNA (ssDNA). DNAse I has been used to specifically degrade DNA in nucleic acid mixtures when only RNA is of interest. RNAses are very stable enzymes that are difficult to remove. As common laboratory contaminants, they make RNA analysis difficult.

Restriction Endonucleases

Restriction endonucleases are found in bacteria; these enzymes degrade foreign DNA. Their action is sequence specific, requiring recognition sequences of usually 4 to 10 nucleotides on a dsDNA molecule. At each location where this sequence is found, the enzyme cuts both strands in a reproducible manner, resulting in either staggered or blunt-end cuts. For example, EcoRI is a restriction enzyme from E. coli that recognizes the six-base sequence GAATTC and cuts between the G and the A on both strands, producing a staggered cut:

$$5' \square\ G/AATTC \square\ 3'$$

$$3' \square\ CTTAA/G \square\ 5'$$

Note that "blunt-end" cuts would be produced if the enzyme hydrolyzed the bond between A and T.

Restriction enzymes are used for digesting large fragments of DNA into smaller pieces and for preparing DNA from different sources to be joined together in **cloning** procedures. Nicking enzymes are restriction enzymes that cut only one strand of double-stranded nucleic acid. Methylation-sensitive enzymes are restriction enzymes that distinguish between cytosine and 5-methylcytosine. In humans, methylation of cytosine is a common epigenetic modification of DNA and is important because it affects gene expression (see Chapter 47).

Ligases

Ligases catalyze the formation of phosphodiester linkages between two nucleic acid chains. DNA ligases are not sequence specific and require the presence of a complementary **template**. In contrast, RNA ligases used in messenger RNA (mRNA) processing do not require a template but are sensitive to sequence.

Polymerases

Polymerases catalyze the synthesis of complementary nucleic acid polymers using a parent strand as a template. In vitro, these enzymes extend an **oligonucleotide primer** that is annealed to a template strand. Extension requires that the 3′OH of the extending end is free and that nucleotide triphosphates (NTPs) are present. Extension ends if you run out of template or NTPs or if no 3′OH groups are available at the extending end. Thermostable polymerases, such as **Thermus aquaticus (Taq) DNA polymerase**, are essential reagents for the automation of many nucleic acid amplification procedures because

of their stability at high temperatures. Some DNA polymerases also have 3′ to 5′, exonuclease activity, 5′ to 3′ activity, or both. A polymerase with 3′ to 5′ exonuclease activity is able to correct mismatched **base pairs** at the 3′-end of the extending chain. Such proofreading activity increases polymerase *fi*delity by decreasing the number of errors or misincorporated bases. A polymerase with 5′ to 3′ exonuclease activity is able to increase the process ability of a polymerase by cleaving any blocking probes or secondary structures, thereby increasing the number of bases incorporated during each extension.

Reverse Transcriptase

Reverse transcriptase is found in **retroviruses** and catalyzes the synthesis of DNA from either an RNA or a DNA template. Retroviruses have RNA genomes, and reverse transcriptase activity is required as part of their replication. In vitro, reverse transcriptase is used to make complementary DNA (cDNA) copies of RNA and may be used for (1) cloning, (2) probe preparation, and (3) nucleic acid assays.

Amplification Techniques

Techniques that increase (1) the amount of the nucleic acid target, (2) the detection signal, or (3) the probe are referred to as **amplification methods**. Examples of amplification methods are listed in Table 48-1. In **target amplification**, the sequence of interest is copied many times by in vitro methods. Areas outside the target are not amplified. In **signal amplification**, the amount of target stays the same, but the signal is increased. Finally, in probe amplification, the probe is amplified only in the presence of the target. In practice, amplification techniques may achieve more than a million-fold amplification in less than an hour.

Polymerase Chain Reaction

When the amount of target nucleic acid is increased by synthetic in vitro methods, target amplification occurs. The **polymerase chain reaction (PCR)**[8] is the most widely known and applied target amplification method.

Methodological Details

PCR requires (1) a thermostable DNA polymerase, (2) deoxynucleotides of each base (collectively referred to as **dNTPs**), (3) the target sequence, and (4) a pair of oligonucleotides (referred to as primers) complementary to opposite strands flanking the sequence to be amplified. In the first step, target duplexes are denatured into single strands by heat (Figure 48-1). When the mixture is cooled, primers provided in great excess (usually more than a million times the concentration of the initial target) specifically anneal to complementary sequences on the target. Once the primers are annealed, the action of the polymerase synthesizes two additional DNA strands containing the primers as the 5′ ends. The primers are placed close enough together so that the polymerase extends each strand far enough to include the priming site of the other primer. Usually the optimum temperature for polymerization is at an intermediate temperature between the denaturation and annealing temperatures. The second cycle also begins with denaturation, but now there are twice as many strands (the original genomic DNA and the extension products from the first cycle) available for primer annealing and subsequent extension. The temperature cycling is typically continued among three temperatures: (1) a high temperature sufficient to denature the target sequence, (2) a low temperature that allows annealing of the primers to the target, and (3) a third temperature that is optimum for polymerase extension. The instrument that takes samples through the multiple steps of changing temperature is known as a **thermocycler**.

Repetitive thermocycling results in the exponential accumulation of the short product (consisting of primers and all intervening sequences). If the efficiency of each cycle is optimal, the number of target sequences doubles each cycle (efficiency expressed as 1.0 or 100%). PCR efficiency depends on (1) the concentrations of the primers and polymerase, (2) the temperature-cycling protocol, and (3) any polymerase inhibitors. Amplified products accumulate exponentially in the beginning cycles of PCR. At some point, however, the efficiency of amplification falls, and eventually the amount of product plateaus (Figure 48-2) either from (1) exhaustion

TABLE 48-1 Common Amplification Techniques

Method	Abbreviation	Type	Enzymes Required
Polymerase chain reaction	PCR	Target	DNA polymerase
Reverse transcriptase PCR	RT-PCR	Target	Reverse transcriptase, DNA polymerase
Transcription mediated amplification	TMA	Target	Reverse transcriptase, RNAse H, RNA polymerase
Ligase chain reaction	LCR	Target	DNA ligase
Strand displacement amplification	SDA	Target	DNA polymerase, restriction enzyme
Loop-mediated amplification	LAMP	Target	DNA polymerase
Whole genome amplification	WGA	Target	Processive DNA polymerase
Antisense RNA amplification	asRNA	Target	Reverse transcriptase, RNAse H DNA polymerase, RNA polymerase
Branched DNA	bDNA	Signal	Alkaline phosphatase
Serial invasive signal amplification	SISAR	Signal	Structure-specific 5′-nuclease
Rolling circle amplification	RCA	Probe	DNA ligase processive DNA polymerase

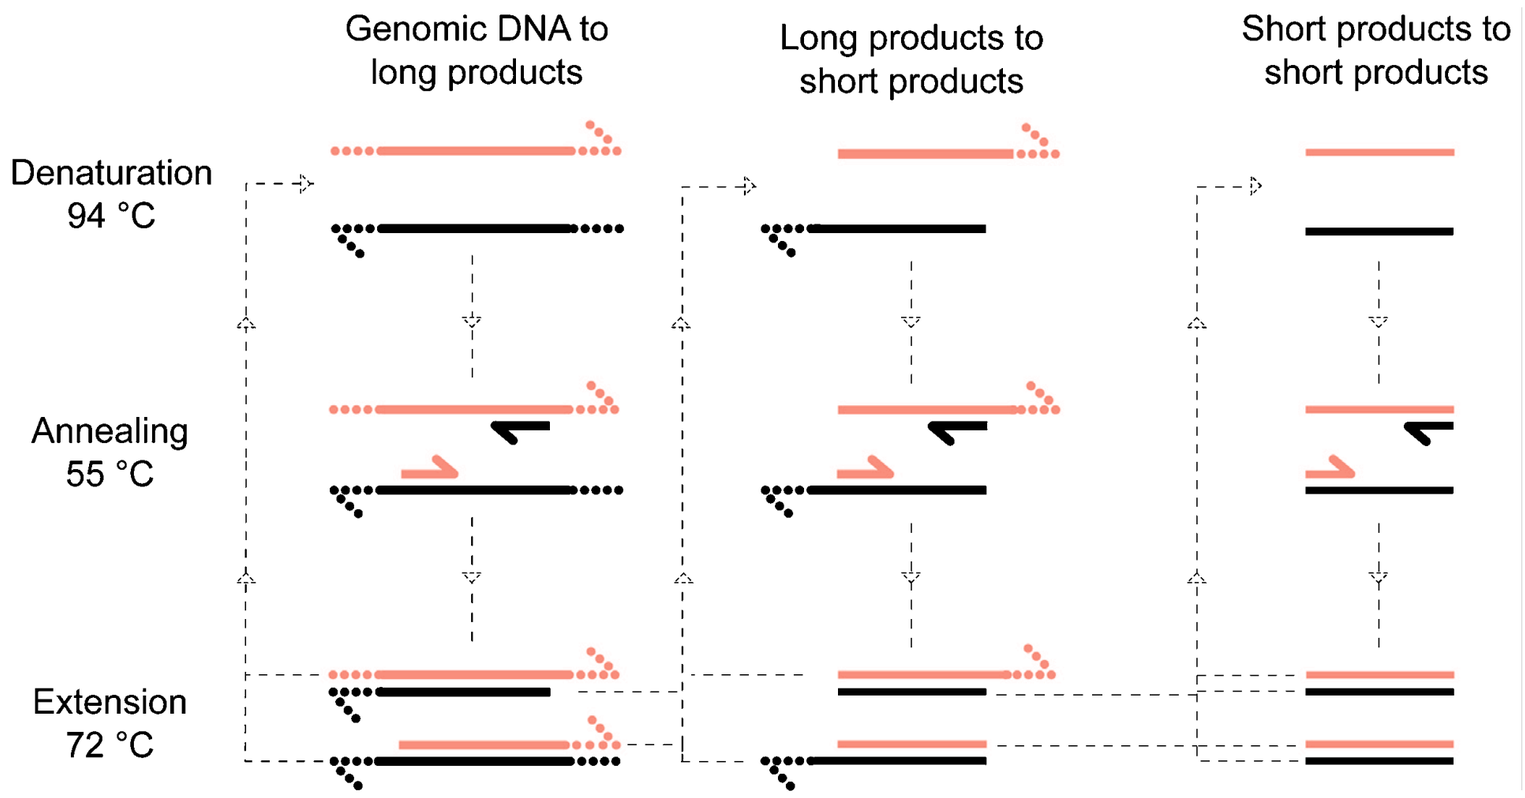

Figure 48-1 Schematic diagram of the polymerase chain reaction (PCR). Repetitive cycles of denaturation, annealing, and extension are paced by temperature cycling of the reaction. Two primers (indicated as short segments with half arrowheads) anneal to opposite template strands (long heavy lines) to define the region to be amplified. Extension occurs from the 3′ ends (indicated with half arrowheads). In each cycle, genomic DNA is denatured and annealed to primers that extend in opposite directions across the same region, producing long products of undefined length. Long products generated by extension of one of the primers anneal to the other primer during the next cycle, producing short products of defined length. Any short products present also produce more short products. After n cycles, 2^n new copies of the amplified region (n long products + $[2^n - n]$ short products) are generated from each original genomic copy. A similar approach is used to amplify RNA targets by initial reverse transcription of the RNA template to produce the DNA template.

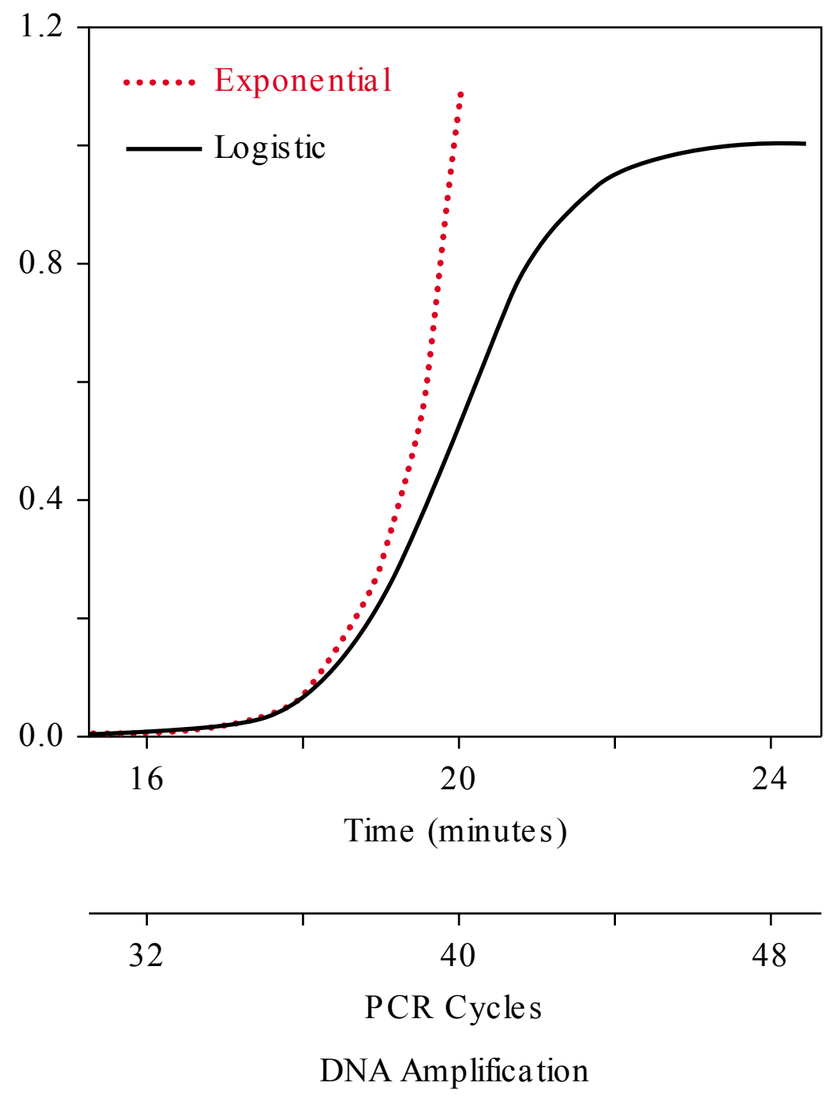

Figure 48-2 Exponential and logistic curves for DNA amplification by polymerase chain reaction (PCR). A doubling time of 30 seconds is assumed for PCR. That is, given the equation $N_t = N_0 e^{rt}$, in which N_t is the amount of DNA at time t and N_0 is the initial amount of the DNA, r is 1.386 min^{-1} for PCR. A carrying capacity of 10^{11} copies of PCR product per microliter was used, assuming that the reaction is primer limited at one third the primer concentration (initially at 0.5 8 mol/L, or 10^{11} primer molecule pairs per microliter). Starting with one target copy, it takes 23 minutes (46 cycles) to amplify the target to saturation. (Modified with permission of the publisher from Wittwer CT, Kusukawa N. Real-time PCR and melting analysis. In Persing DH, Tenover FC, Tang YW, Versalovic J, Nolte FS, Hayden RT, Belkum AV [eds.], Molecular microbiology: diagnostic principles and practice, 2nd edition, Washington, DC: ASM Press, 2011:63-82. © 2011 ASM Press.)

of components or (2) from competition between primer and product annealing as the single strands of product are at such high concentrations that they anneal to each other rather than to the primers. The S-curve shape is similar to the logistic model for population growth. In a typical PCR reaction using 0.5 μmol/L of each primer, the maximum DNA concentration achievable is about 10^{11} copies/μL.

After amplification, the products are detected by various methods. Simple gel **electrophoresis** with ethidium bromide staining provides an approximate size of the PCR product. When greater accuracy is required, one of the primers is fluorescently labeled so that after PCR the fragments are able to be sized on a DNA **sequencing** device. Alternatively, some form of **hybridization** assay is used to verify or analyze the amplified product. Automated methods are available, and closed-tube methods are particularly advantageous in the clinical laboratory. Adding a fluorescent dye or probe before amplification allows thermocyclers equipped with optical detection to analyze the reaction as it progresses (**real-time PCR**) or after the reaction is complete (end point or equilibrium measurement) without need to process the sample for a separate analysis step.

Kinetics and Rapid Cycling

A typical cycle of PCR requires (1) denaturation of double-stranded target, (2) annealing of primers to their targets, and (3) extension of the DNA strand from the primer. In practice, each of these steps occur at a selected temperature, for example, (1) denaturation at 94 °C, (2) annealing at 55 °C, and (3) extension at 72 °C, and for a chosen duration. Standard thermocycling instruments focus on accurate temperature control at equilibrium, not on the dynamic control of the sample temperature during transitions. As a result, long cycle times have become standard to ensure that the sample reaches target temperatures and PCR may require hours to complete typical 30-cycle amplifications.

However, the kinetics of PCR suggest that controlled transitions between temperatures with minimal or no pauses (temperature plateaus) are optimum for PCR amplification (Figure 48-3). Thus, denaturation, annealing, and extension are very rapid reactions. The use of temperature "spikes" at denaturation and annealing, instead of extended temperature plateaus, allows for rapid cycling. The actual time required for PCR depends on the size of the product, but when it is less than 500 base pairs (bp), a 30-cycle amplification is easily completed in 15 to 30 minutes. Furthermore, rapid amplification improves specificity. Figure 48-4 shows PCR amplification of a 536-bp fragment of β-globin amplified at different cycling speeds. With conventional slow cycling, many nonspecific products are generated (cycling profile A). These products disappear as the cycling time is decreased (profiles B, C, and D). In fact, amplification yield and product specificity are optimal when denaturation and annealing times are minimal. Most PCR is slow because of instrument limitations. In contrast, the biochemical components of PCR are rapid, and extremely fast PCR is now feasible (<1 min).[14]

Detection Limits

When PCR is performed under optimal conditions, it is possible to detect a single copy of the target. In practice, however, the chance of getting one or more copies from a dilute template solution into individual reactions must be considered. The Poisson distribution (a discrete probability distribution) indicates that if, on average, one target copy will be present per

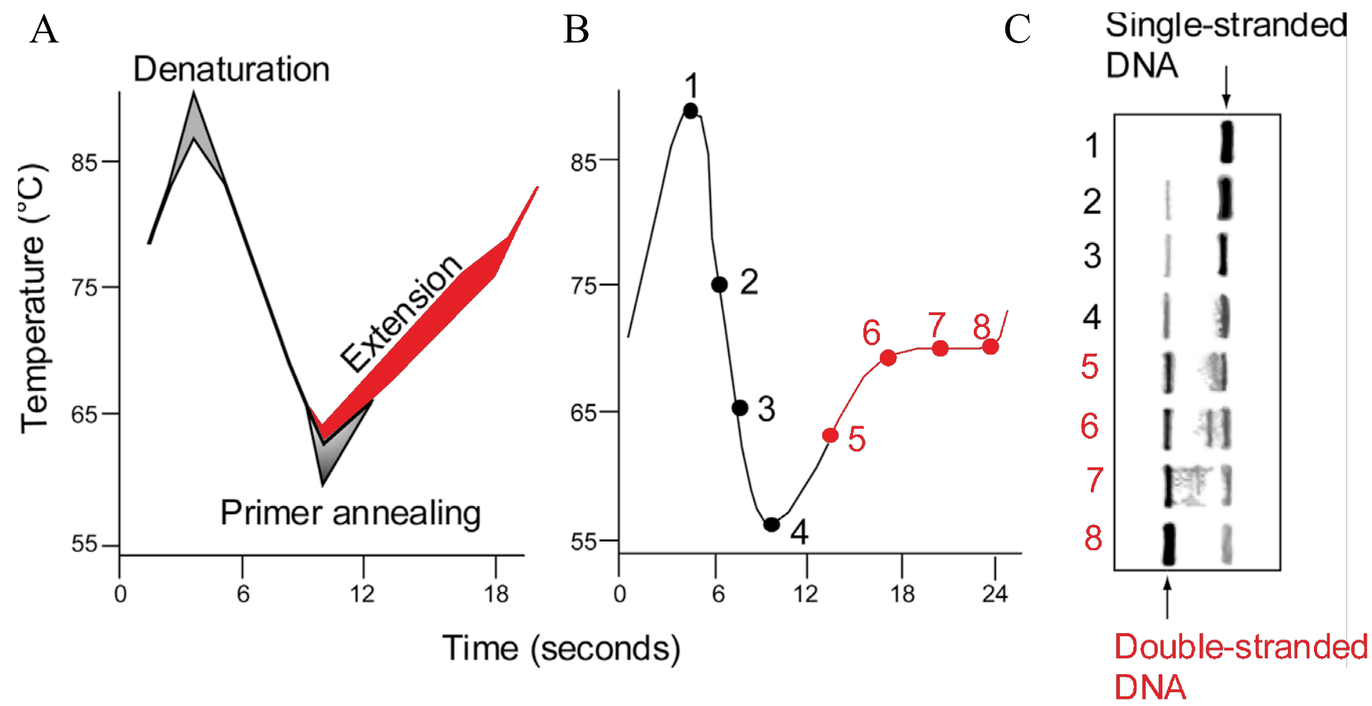

Figure 48-3 A visual demonstration of polymerase chain reaction (PCR) kinetics. The three phases of PCR (denaturation, annealing, and extension) occur as the temperature is continuously changing (panel A). Toward the end of PCR temperature cycling, the reaction contains single- and double-stranded PCR products. When different points of the cycle are sampled (by snap cooling the mixture in ice water, panel B) and analyzed, the transition from denatured single-stranded DNA (ssDNA) to double-stranded DNA (dsDNA) is revealed as a continuum (panel C). Progression of the extension reaction can be followed by additional bands appearing between the ssDNA and dsDNA (time points 5 to 7). (Modified with permission from Wittwer CT, Herrmann MG: Rapid thermal cycling and PCR kinetics. In Innis M, Gelfand D, Sninsky J, eds. PCR applications, San Diego: Academic Press, 1999:211-229. © 1999 Academic Press.)

tube, 37% of the tubes will have no target, 37% will have one target, and the remainder will have more than one. If there is an average of two copies per tube, approximately 14% of the tubes will have no template and will provide a false-negative result. About five copies on average are necessary for 99% of the tubes to include at least one copy. In practice, single-molecule PCR has been used to overcome these sensitivity limits.

Single-molecule PCR/Digital Polymerase Chain Reaction[5]

Single-molecule PCR (also known as **digital polymerase chain reaction** (digital PCR)) is a technique that limits the amount of template that is distributed across many reaction compartments so that some compartments have no template. Digital PCR depends on an on-of signal resulting from either the presence or absence of template in each of many reactions. Instead of conventional tubes, these compartments may be (1) very small droplets in a water-in-oil emulsion (emulsion PCR), (2) PCR colonies (polonies) within a gel, (3) on the surface of a flowcell, or (4) on microbeads. When thousands of reactions are analyzed, it is possible to obtain very exact quantification. For example, copy number changes and rare mutations in a population of tumor cells are easily quantified.[14] T e clonal nature of digital PCR allows one to assess whether multiple variants are on the same or dif erent chromosomes. Single-molecule PCR is also used as the first step for many of the high-throughput sequencing methods reviewed later in this chapter.

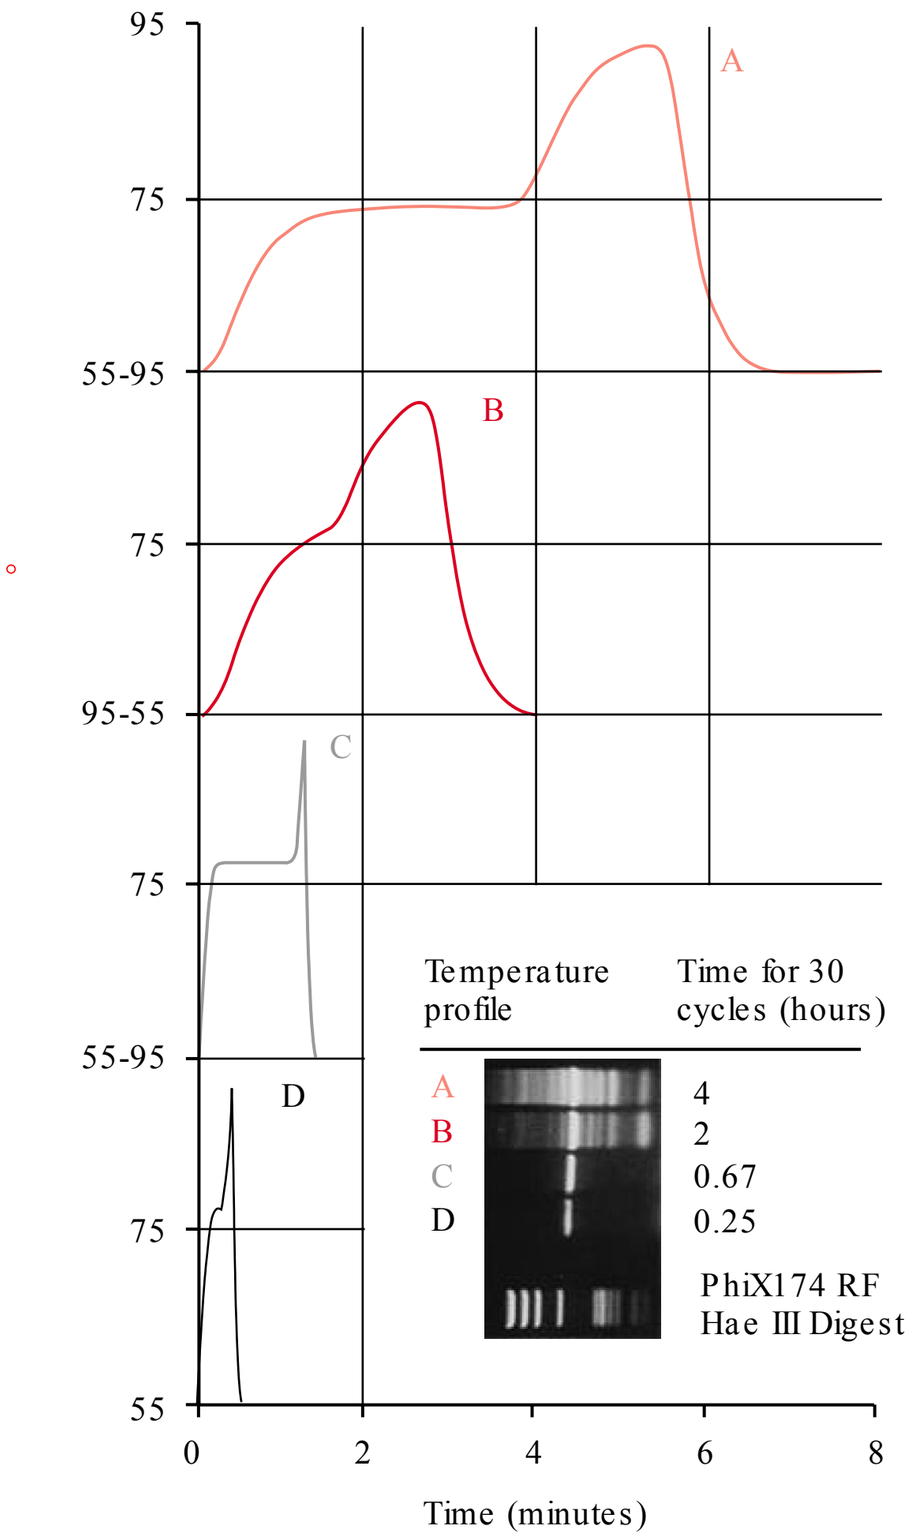

Figure 48-4 Rapid polymerase chain reaction (PCR) improves product specifcity. Samples were cycled 30 times through profiles A, B, C, and D. Increased specificity of amplification of a 534 bp β-globin fragment is seen with faster cycles (C and D). (Reprinted by permission of the publisher from Wittwer CT, Garling DJ: Rapid cycle DNA amplification: time and temperature optimization. BioTechniques 1991, 10:76-83. © 1991 Eaton Publishing.)

Contamination Control (False-Positive)

Because PCR is able to detect a single molecule of target sequence, a small amount of contamination in a sample easily produces a false-positive result. T e greatest potential for contamination comes from the product of the amplification reaction, referred to as the **amplicon** (used interchangeably with PCR product). After amplification, each reaction mixture may contain as many as 10^{12} copies of the amplicon. T us minute aerosol droplets contain more than enough target for robust amplification. Amplicons contaminate (1) reagents, (2) pipettes, and (3) glassware. Simple laboratory precautions that have been utilized to minimize contamination by amplicons include the use of (1) physically separated areas for preamplification and postamplification steps, (2) positive-displacement pipettes to minimize aerosol contamination, and (3) prealiquoted reagents. T e most ef ective way of all is to contain the product in a closed tube and not let any escape. Even with these precautions, a negative control or blank (all reactants minus target DNA) is an important feature of a quality control program for monitoring PCR.

Inhibition Control (False-Negative Results)

An advantage of PCR is that it does not require highly purified nucleic acid to achieve a successful amplification. In practice, however, clinical samples may contain unpredictable amounts of impurities that could inhibit polymerase activity. Consequently to ensure reliable amplification in clinical analyses, some form of nucleic acid purification is often used. T e diverse nature of PCR inhibitors within clinical specimens requires demonstration that the sample (or preparation of nucleic acid purified from it) will allow amplification. Typically, a control nucleic acid sequence, usually dif erent from the target, is added to the sample (or to nucleic acid extracted from the sample). Failure to amplify this control indicates that further purification of the sample is required to remove inhibitors of the reaction.

Asymmetric and Allele-Specifc Polymerase Chain Reaction

Conventional PCR uses primers that are present in equal amounts, thereby ensuring that the majority of the products are double-stranded amplicons. **Asymmetric PCR** uses different concentrations of the two primers to generate more of one strand than of the other so that the single stranded product is able to be directly hybridized to probes without denaturation.

Another variant method called **allele-specific PCR** enables preferential amplification of one genetic allele over another. The 3′ end of one primer is placed at the polymorphic site and is extended readily only if it is completely complementary to the target. This strategy is useful for distinguishing a gene from its **pseudogenes** and for genotyping of SNVs.

Additional Amplification Methods

In addition to PCR, many other methods for amplification have been developed, and some are briefly described below. Citations to the original literature are available elsewhere.[14]

Transcription Mediated Amplification

Transcription mediated amplification (TMA) is modeled after the replication of retroviruses. The target is isothermally amplified without temperature cycling and a reverse transcriptase, RNAse H, and RNA polymerase are required. As illustrated in Figure 48-5, the method may be applied to single-stranded RNA or dsDNA targets. As in PCR, all reagents are included and amplification is exponential with completion in less than an hour. Unlike PCR, temperature cycling is not required, although an initial heat denaturation is needed if a dsDNA template is used. The method is particularly advantageous when the target is a viral RNA from patients carrying the human immunodeficiency virus [HIV] or hepatitis C virus [HCV] in blood bank nucleic acid testing.

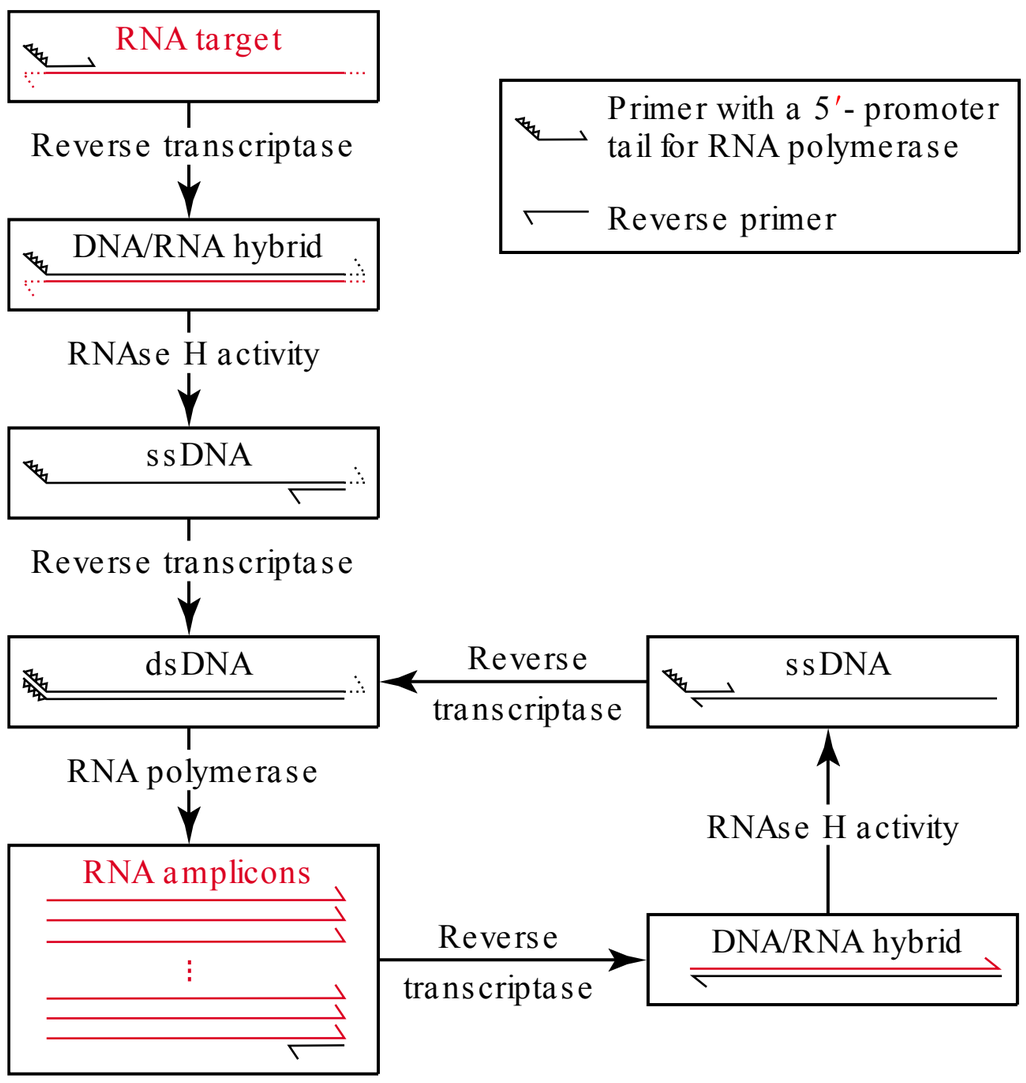

Figure 48-5 Schematic diagram of transcription mediated amplification (TMA). Starting with a single-stranded RNA target, a primer with an RNA polymerase promoter on its 5′-end is extended by reverse transcriptase to form a DNA/RNA hybrid. The reverse transcriptase also has RNAse H activity that subsequently degrades the RNA strand to leave single-stranded DNA (ssDNA). A second primer then binds to the ssDNA, and extension forms double-stranded DNA (dsDNA) with the attached RNA polymerase promoter. RNA polymerase then makes 100 to 1000 copies of RNA, some of which are again primed by the second primer. Repeated cycles of reverse transcription, DNA/RNA hybrid degradation by RNAse H activity, ds-DNA formation by reverse transcriptase, and further transcription by RNA polymerase exponentially produce ssRNA amplicons. Single-stranded targets are amplified isothermally, while double-stranded targets are first denatured to single strands.

Additional Target Amplification Techniques

Additional target amplification techniques include (1) the **ligase chain reaction (LCR)**, (2) **strand displacement amplification (SDA)**, and (3) **loop-mediated amplification (LAMP)**. In the LCR, a ligase replaces the polymerase of PCR, resulting in exponential ligation during temperature cycling. In SDA, strand displacement is used instead of thermal denaturation, allowing isothermal amplification. LAMP also uses strand displacement and is isothermal, producing a myriad of looped structures of different sizes. All target amplification methods increase the concentration of target sequences so that they are easier to detect.

Whole Genome, Transcriptome, or Exome Amplification

Instead of specific amplification of one target to improve sensitivity, methods that amplify all nucleic acids of a specific class are useful when the target is in short supply. For example, **whole genome amplification** (WGA) uses random hexamers and a highly processive polymerase to amplify DNA nonspecifically. Similarly, it is possible to generically select, amplify and sequence an **exome** or **transcriptome** by first isolating the respective RNAs. For example, it is possible to reverse transcribe mRNA by use of a poly(T) primer modified with an RNA polymerase promoter. After reverse transcription, second-strand DNA synthesis, and transcription, **antisense RNA (asRNA)** is produced that is then used in expression studies. Whole genome, transcriptome and exome amplification are useful to enrich and amplify before detection or sequencing

Branched-Chain Signal Amplification

The **branched-chain signal amplification technique** creates branched DNA (bDNA) by hybridizing the target nucleic acid to multiple capture probes affixed to a microtiter well. This is followed by hybridization to a series of (1) "extender," (2) "preamplifier," and (3) amplifier probes. The final, highly-branched amplifier probe includes multiple copies of signal-generating enzymes that act on a chemiluminescent substrate to produce light.

Signal and Probe Amplification Methods

Signal and probe amplification methods are also used in molecular diagnostics. For example, **serial invasive signal amplification** is a target-dependent signal amplification method used for SNV genotyping that generates **fluorescence** by recycling the cleavage of primary and secondary probes. **Rolling circle amplification** (RCA) is a probe amplification method. In the presence of template, a linear probe is ligated to form a circle that is replicated continuously by a polymerase

and one or more primers. The amplified probe is then detected and indicates the presence of the target.

Quantification after Amplification

Quantitative analysis at the end of amplification usually requires **calibration** with known amounts of target or a target mimic. Quantification is accomplished by comparison to an internal standard that is added at the time of sample processing to control for losses during nucleic acid purification. Examples of internal standards are (1) DNA fragments, (2) plasmids, and (3) RNA packaged into synthetic phage or virus particles to mimic the assay of real viruses ("armored" RNA). If the competitor template is amplified by the target primers but generates an amplicon with a sequence or size different from the target amplicon, any variation in reaction activity affects both products identically. Thus, both are amplified. Real-time PCR, however, is a simpler and more powerful approach to quantification than end-point assays. The reaction is monitored each cycle, and the profiles of the curves are used to calculate initial target concentrations. Details of **real-time PCR** are described later in this chapter.

Detection Techniques

Molecular diagnostics relies on both generic and specific **detection methods** for nucleic acids. Generic techniques measure the total amount of nucleic acid, whereas specific techniques measure a particular sequence often by the use of nucleic acid probes.

Generic Measurement and Visualization

To generically measure or visualize nucleic acids, ultraviolet (UV) spectrophotometry and fluorometry combined with fluorescent staining dyes are commonly used.

Ultraviolet Spectrophotometry

Nucleic acid molecules absorb UV light maximally at 260 nm, a property that is often used to measure the nucleic acid content of a solution. If a dsDNA preparation is pure, a 50 mg/L solution has an absorbance of 1.0 at 260 nm. Also, the purity of a nucleic acid preparation can be assessed by its absorbance ratio at 260 nm and 280 nm (260:280 ratio). In contrast to nucleic acids, proteins absorb maximally at 280 nm. A pure DNA sample should have a 260:280 ratio of 1.7-2.0. Lower values suggest significant protein contamination.

Fluorometry and Fluorescent Staining

Although absorbance measurements are simple and precise, they often are not sensitive enough for generic measurement and visualization applications. Consequently, fluorometric and fluorescent staining techniques are often used to measure nucleic acids as they are 1000 to 10,000 times more sensitive than absorbance measurements. A widely used fluorescent nucleic acid dye is ethidium bromide, a positively charged, intercalating dye for dsDNA and to a lesser extent, ssDNA and RNA. Cyanine dyes, such as SYBR Green I, are also popular stains for nucleic acids because they do not fluoresce unless they are bound to nucleic acids, thus providing very low background. With the appropriate optics, it is possible to visualize single molecules of DNA with cyanine-based nucleic acid stains.[6]

Sequence Specific Labels

Sequence-specific labels are used to discriminate between different nucleic acid sequences, and many types of labels have been covalently attached or incorporated into nucleic acid to form probes. The first probes used in nucleic acid detection were radioactively labeled. Radioactive labels are still favored in some research settings because of the sensitivity obtained with probes of high specific activity. However, radioactive probes are limited by isotopic decay and radiolysis of the nucleic acid. This is inherent instability, along with concerns of radioisotope safety and disposal, restricts the use of radioactive probes in the clinical laboratory.

Biotin or digoxigenin are commonly used nonradioactive probes that are usually labeled at the 3′ or 5′ end of the molecule to minimize interference with hybridization. Such affinity labels do not generate signals on their own, but require high-affinity binding partners like antibodies or streptavidin. These high affinity binding molecules are often linked to enzymes with substrates that produce (1) chemiluminescent, (2) spectrophotometric, or (3) fluorescent signals.

In practice, affinity labels have been used to capture and localize targets to a solid support. For example, biotinylated probes may be affixed to a streptavidin-coated surface. After incubation with the target nucleic acid, a second probe is added, which is either directly labeled with a fluorescence chemical or conjugated through an affinity label to an enzyme. Any background or nonspecific localization of reagents results in amplification of an undesired signal along with the desired signal, and these methods usually require multiple separation and washing steps to decrease the background.

Advances in oligonucleotide synthesis and fluorescence detection have made fluorescene-labeled probes the preferred reporter for nucleic acid analysis. Many fluorescent labels are now available, allowing color multiplexing for applications, such as (1) DNA sequencing, (2) fragment length analysis, (3) DNA **arrays**, and (4) real-time PCR (all reviewed later in this chapter). Techniques such as (1) fluorescence polarization, (2) fluorescence resonance energy transfer (FRET), and (3) fluorescence quenching provide additional detection specificity.

Discrimination Techniques

Widely-used general categories of nucleic acid discrimination are:

- Electrophoretic separation: Provides physical separation of individual nucleic acid species based on molecular weight and shape.
- Discrimination by size or sequence without use of electrophoresis. Examples are (1) high-performance liquid chromatography (HPLC), (2) mass spectrometry, and (3) high throughput sequencing.
- Hybridization assays: Provides visualization of specific nucleic acids out of a background, usually with probes. Some techniques use both electrophoresis and hybridization.

Electrophoresis

Electrophoresis (see Chapter 11) is the most commonly used method for separating molecules of DNA and RNA. Both DNA and RNA are negatively charged and will migrate toward the positively charged electrode when an electrical field is present within an appropriately buffered solution. Separation of different nucleic acids occurs when mixtures are allowed to travel through a neutral sieving polymer under the electrical field. Separation is primarily based on molecular weight with smaller molecules traveling faster through the polymer than larger ones (Figure 48-6). When very large molecules (≥50 kb) have to be separated, pulsed electrical fields are employed to help move these molecules through the polymer matrix. Separation also occurs based on the physical conformation, or shape, of the molecule. For instance, single-stranded molecules may fold into secondary structures, and double-stranded molecules may form (1) **heteroduplexes**, (2) nicked strands, or (3) superhelical circular structures. Separation based on shape provides useful information, but sometimes confuses size-based analysis. For instance, because RNA generally has a high degree of secondary structure, electrophoresis of RNA is usually performed under denaturing conditions to abolish these secondary structures. Electrophoresis of DNA is performed under native or denaturing conditions depending on the application.

RNA electrophoresis is commonly performed as a quality control check before transcript quantification or microarray expression analysis. As RNA is degraded easily by tissue or environmental RNAses, it is important to assess the quality of the RNA used in these methods. Because RNA often has secondary structure, electrophoresis is usually performed under denaturing conditions to eliminate them. Microfluidic chips with integrated microelectrophoresis are commercially available to rapidly assess RNA integrity by inspection of ribosomal RNA peaks (Figure 48-7). In practice, only small amounts of starting RNA are needed by this method. However, it does not detect specific transcripts.

Agarose gels and polyacrylamide are the two types of polymeric support medias commonly used in electrophoresis. Agarose gels are able to separate nucleic acid fragments as small as 20 bp to more than 10 Mb (10,000 kb), including chromosomes of (1) yeast, (2) fungi, and (3) parasites. However, the resolution of separations in agarose is limited, usually to a size difference of 2% to 5%. Polyacrylamide polymers are suited for high-resolution separation (down to about a 0.1% size differences) of short molecules (up to about 2 kb) and are the primary polymer for single-stranded nucleic acid separation, such as DNA sequencing. Table 48-2 lists common electrophoresis-based techniques described further in this section.

Polymerase Chain Reaction Product Length

The analysis of PCR product by electrophoresis is frequently used to assess the quality and specificity of PCR amplification. PCR products are visualized by staining the gel with a fluorescent DNA-binding dye, such as ethidium bromide. In some situations, the presence of an amplification product is directly diagnostic, such as the detection of sequences found only in a (1) bacterium, (2) virus, or (3) fungus in a human sample. The specificity of the amplification reaction is verified by the known size of the fragment. Internal negative and positive controls are used to control for potential contamination and to establish detection sensitivity.

Monitoring of the PCR product length on gels allows detection of (1) small **insertions**, (2) deletions, (3) rearrangements,

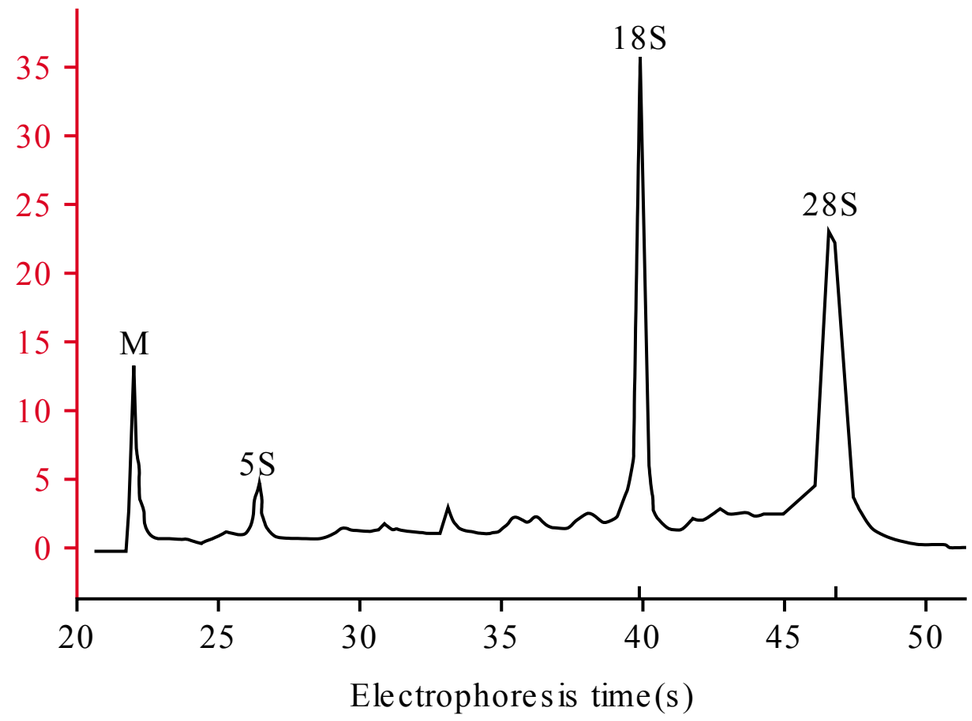

Figure 48-7 Microelectrophoresis of human white blood cell RNA. After isolation of white blood cells and extraction of total RNA, samples were denatured, stained with a fuorescent dye, and applied to a commercial microelectrophoresis platform for assessment of RNA quality. Prominent 18S and 28S bands of ribosomal RNA suggest the RNA is largely intact. Also indicated are a reference marker (M) and the 5S ribosomal band. Note that electrophoresis was performed in less than 1 minute.

and (4) changes in the number of repeated sequences. Length differences may be large and easily detected with agarose gel electrophoresis, or they may be small enough to require a denaturing polyacrylamide support matrix. Fluorescent primers may be incorporated into the product during PCR to simplify detection of fragment lengths. These techniques are commonly used in the diagnosis of inherited diseases and in identity assessment.

Restriction Fragment Length Polymorphism

DNA extracted from a cell is extremely long and is usually cut into shorter fragments before electrophoresis to aid the analysis. For example, restriction endonucleases cut dsDNA into fragments of reproducible size and the same enzyme produces the same fragments in different specimens if the specimens contain the same DNA sequence. If an alteration in the DNA abolishes or creates a cleavage site recognized by the enzyme (or changes the spacing between two cleavage sites), then the digested fragments will have different lengths: hence, the name **restriction fragment length polymorphism (RFLP)**. However, restriction digestion produces thousands of fragments. To be useful, specific fragments need to be visualized.

The **Southern blot** technique separates restriction fragments by agarose gel electrophoresis and transfers by blotting them to a membrane for selective visualization by labeled probes. The hybridized probes then are visualized by autoradiography or chemiluminescence. Southern blotting detects RFLPs, including large structural alterations, such as (1) deletions, (2) duplications, (3) insertions, and (4) rearrangements. The procedure was named after its inventor, E. M. Southern, and it was the first discrimination method with adequate sensitivity and specificity for DNA analysis of single-copy genes in complex genomes. However, it requires large amounts of DNA (10-50 µg/lane) and is labor intensive and time consuming. Today, it has largely been replaced by PCR-based assays.

TABLE 48-2 Commonly Used Electrophoresis-Based Techniques

Technique	Abbreviation	Use
PCR product length		Detection
Southern blotting		Detection, Quantification
PCR/Restriction fragment length polymorphism	PCR/RFLP	Genotyping
Conformation-sensitive gel electrophoresis	CSGE	Scanning
Denaturing gradient gel electrophoresis	DGGE	Scanning
Temperature gradient gel electrophoresis	TGGE	Scanning
Single-stranded conformational polymorphism	SSCP	Scanning
DNA sequencing (dideoxy termination/Sanger sequencing		Sequencing
Single-nucleotide extension assay	SNE	Genotyping
Oligo ligation assay	OLA	Genotyping
Multiplex ligation-dependent probe amplification	MLPA	Quantification

Polymerase chain reaction/Restriction Fragment Length Polymorphism

PCR can be used to amplify regions of DNA that contain known sequence alterations that alter restriction-enzyme cleavage sites. After PCR, the products are digested with one or more restriction enzymes and analyzed by electrophoresis. For example, if a sample has a variant (such as a mutation) that disrupts a restriction-enzyme recognition site, this is distinguished from a sample that does not have the variant. Such an assay will produce one uncut PCR fragment when the mutation is present and two shorter fragments when the mutation is absent (Figure 48-8). If the variant is present as a heterozygote (e.g., one normal and one mutant copy of DNA), then one long and two shorter fragments will be observed. Typically the assay is designed such that the fragments are easily resolved by agarose electrophoresis and visualized by staining the gel with a fluorescent DNA-binding dye, such as ethidium bromide. One variant of this technique uses reverse-transcribed mRNA, which lacks the **introns** that would be present in the DNA. It is possible to analyze multiple exons in one PCR.

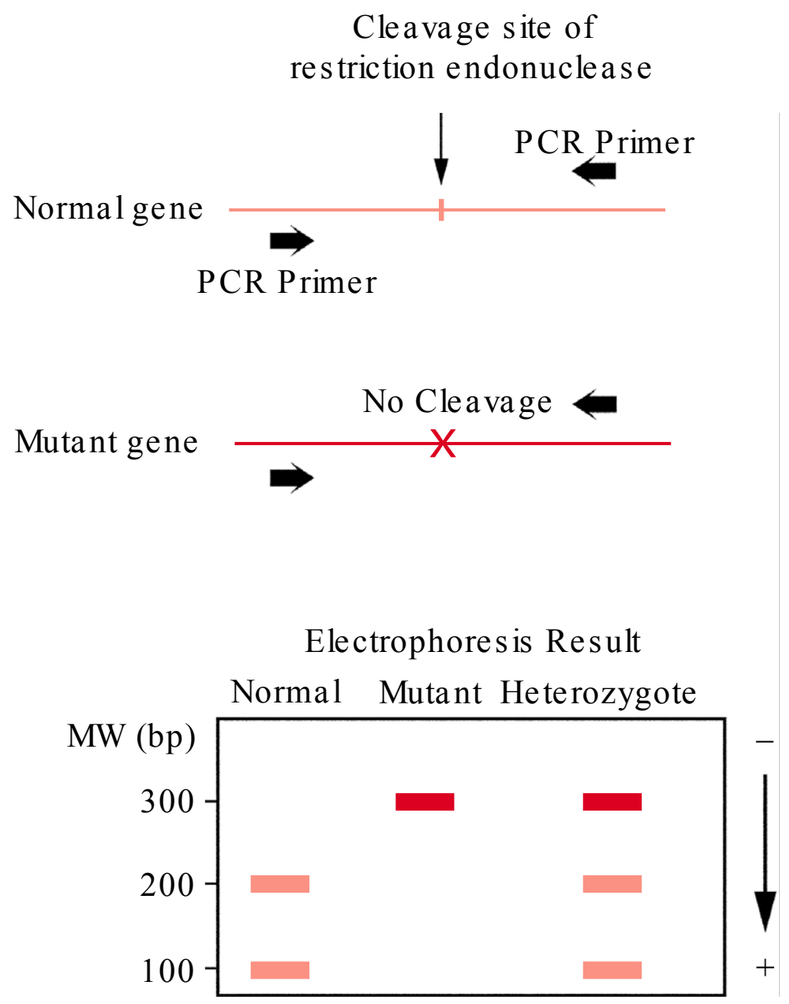

Figure 48-8 An example of polymerase chain reaction–restriction fragment length polymorphism (PCR–RFLP). A DNA fragment amplified by PCR carries a site (a unique sequence of generally four or more bases) that is recognized and cleaved by a specific restriction endonuclease. If a mutation is present, this site is altered and is no longer recognized by the enzyme. Electrophoresis reveals that the fragment from a normal specimen was indeed cut by the enzyme, generating two fragments shorter than the original length, whereas the fragment from a homozygous mutant was not cut, and the original length of the amplicon was preserved. In a heterozygous mutant, both the original fragment and the shorter fragments are visible.

Conformation-Sensitive Scanning Techniques

Several electrophoretic methods detect sequence variants within PCR products. For example, **hetero-duplex analysis (HDA)** that is also called **conformation-sensitive gel electrophoresis (CSGE)**, reveals the presence of mutations by the altered mobility of a dsDNA fragment that contains one or more mismatched bases (a heteroduplex) versus one that is perfectly matched (a **homoduplex**). Heteroduplexes usually migrate more slowly than homoduplexes during electrophoresis (Figure 48-9). **Denaturing gradient gel electrophoresis (DGGE)** and **temperature-gradient gel electrophoresis (TGGE)** detect heteroduplexes by their lower stability. As the temperature or denaturing gradients are increased, heteroduplexes melt at lower temperatures, and eventually the strands separate, altering the gel migration. CSGE, DGGE, and TGGE depend on altered **heteroduplex** migration. Homozygous variants are not detected unless mixed with a homozygous normal to form heteroduplexes.

Single-stranded conformational polymorphism (SSCP) analysis is another electrophoresis technique used to scan for unknown variants in nucleic acids. After PCR and denaturation, the single DNA strands fold into three-dimensional structures depending on their sequence. Electrophoretic mobility is a function of size and shape of the folded single-stranded molecules. If the sequence of a reference sample differs from that of the fragment being tested, the molecules adopt different conformations and exhibit unique banding patterns. Unlike the heteroduplex methods, homozygous changes are also detected with SSCP.

Scanning methods are useful when a wide variety of sequence alterations might be present. Particularly when most of the samples tested are wild type ("normal"), an initial scan for the presence of mutations before targeted genotyping or sequencing is more efficient.

Dideoxy-Termination Sequencing

Dideoxy-termination sequencing is a method of DNA sequencing based on the selective incorporation of chain-terminating dideoxynucleotides by DNA polymerase during in vitro DNA replication. It is also known as **Sanger sequencing** and is now routinely performed in the clinical laboratory. In addition, it is possible to sequence RNA after conversion to DNA with reverse transcriptase. Using Sanger sequencing, base changes resulting in (1) different amino acid codons, (2) stop codons, (3) deletions, or (4) insertions are identified. The most common sequencing strategy uses PCR in the first step to amplify the region of interest, followed by a variation of the chain-termination reaction developed by F. Sanger in the late 1970s.[9] This reaction generates fragments that are terminated at various lengths by the incorporation of one of the four dideoxynucleotide base analogs (Figure 48-10) during extension from the sequencing primer (Figure 48-11). Dideoxynucleotides lack the 3′ hydroxyl group (OH) and the 2′ OH on the pentose ring. Because DNA chain growth requires the addition of deoxynucleotides to the 3′ OH, incorporation of a dideoxynucleotide terminates chain growth. The most common method for generating these terminated fragments is cycle sequencing by repeating the temperature-controlled steps of (1) annealing, (2) chain extension with termination, and (3) denaturation, similar to PCR. The fragments generated are (1) labeled with fluorescent dyes on the terminating dideoxynucleotides, (2) separated by capillary electrophoresis, and (3) detected by fluorescence as the fragments travel past a detector (Figure 48-12). Dideoxy-termination DNA sequencing in the clinical laboratory is commonly used in infectious disease testing, such as genotyping of HIV to detect mutation

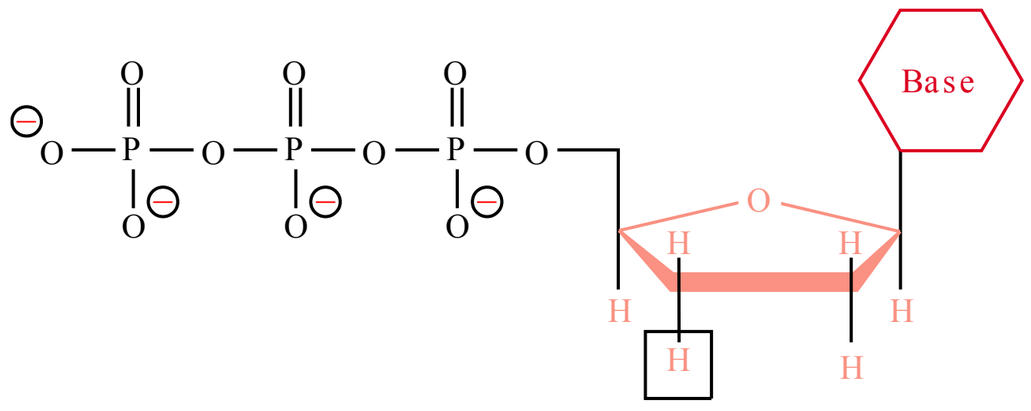

Figure 48-10 A dideoxynucleotide. Notice the absence of the 3′-OH that is usually present in standard deoxynucleotides. Without a 3′-OH, polymerase extension cannot occur.

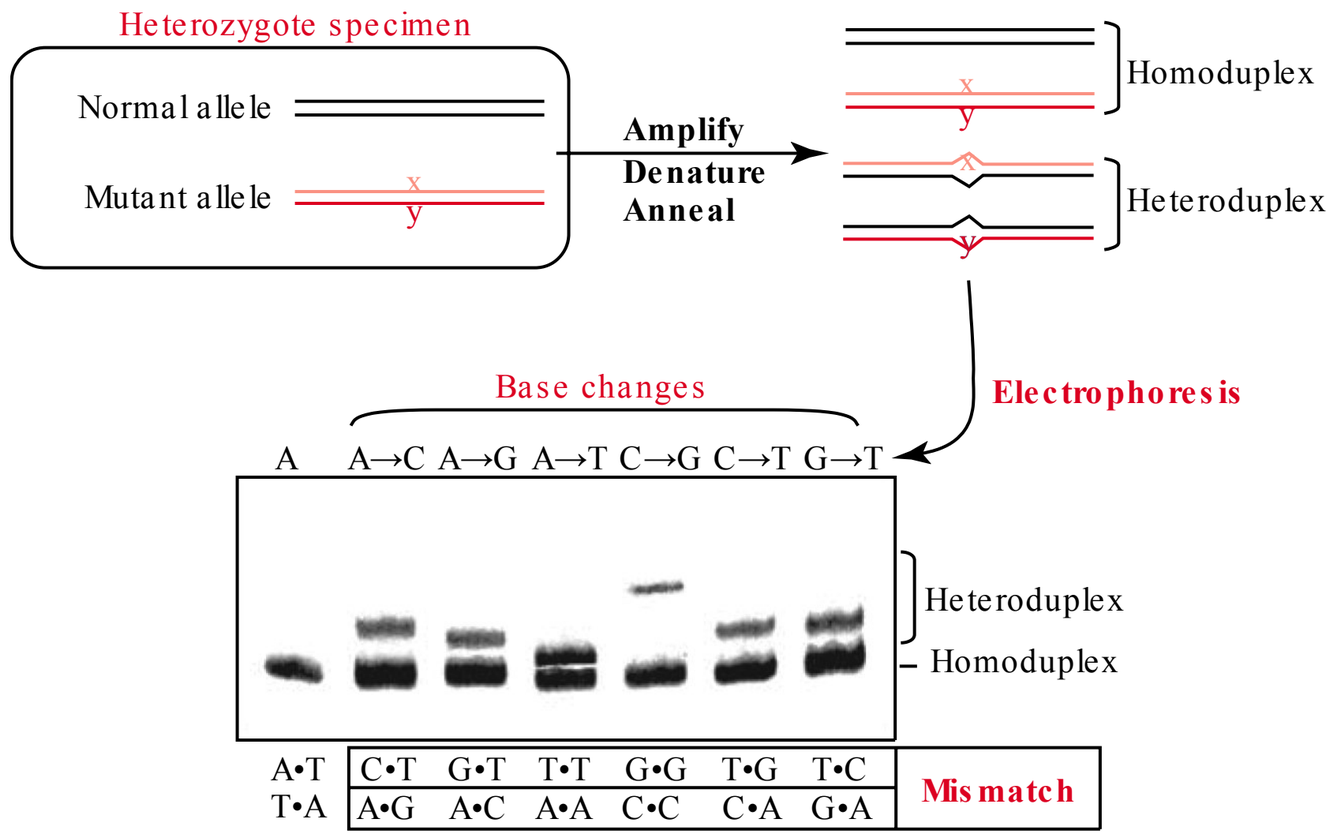

Figure 48-9 A schematic of heteroduplex migration analysis. When amplified DNA from a heterozygous specimen is denatured and cooled, the fragments anneal in four combinations. Electrophoresis on a polyacrylamide gel reveals the presence of heteroduplexes as extra band(s) appearing above the homoduplex band.

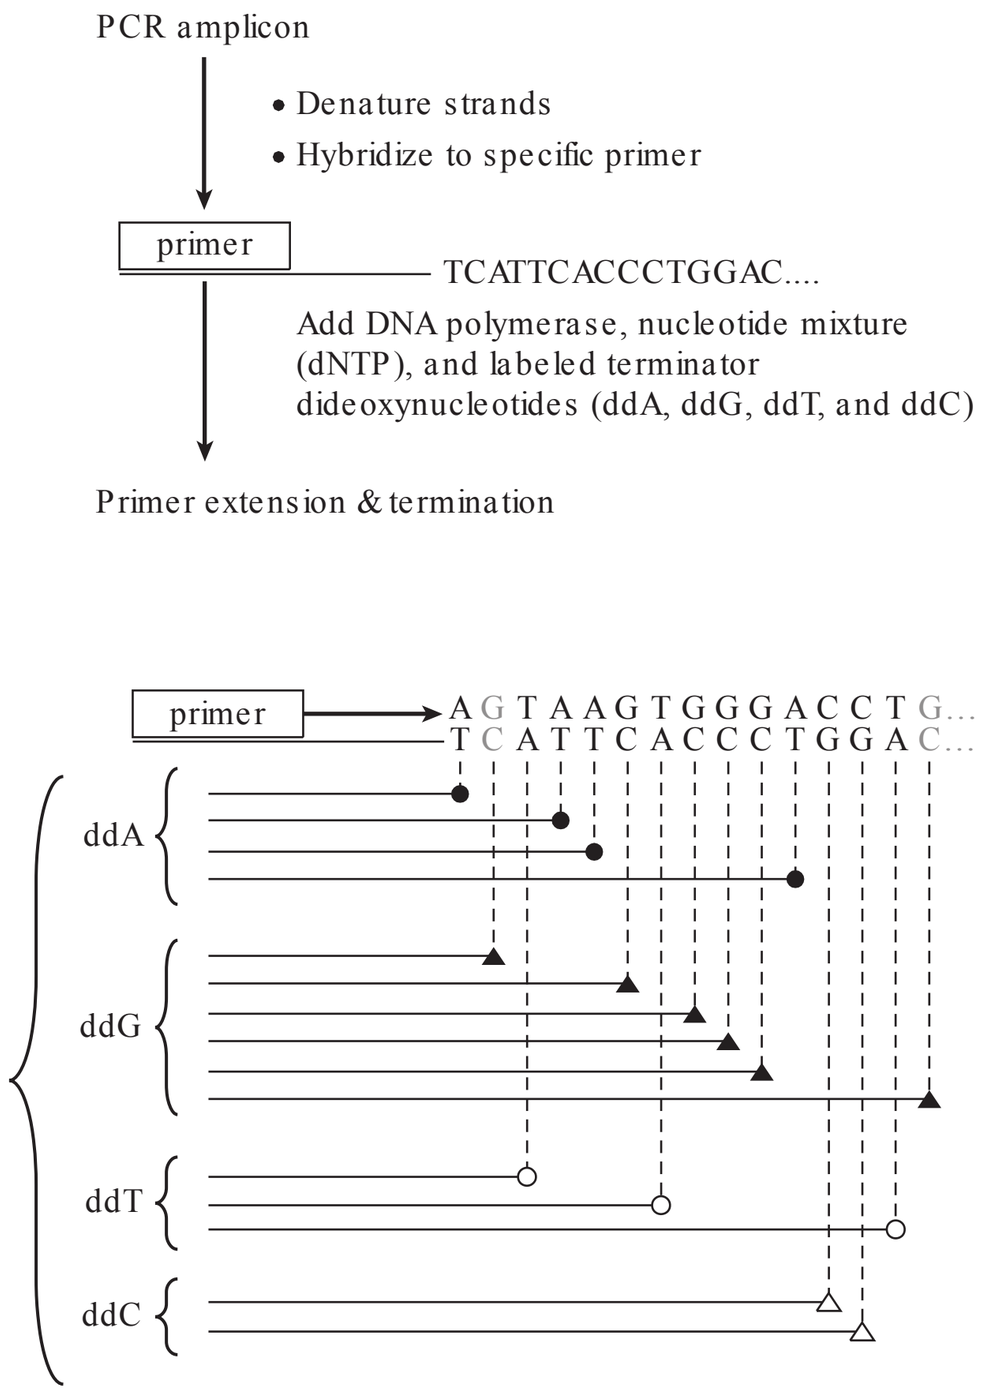

Figure 48-11 The dideoxy-termination reaction for sequencing. A polymerase chain reaction (PCR) amplicon is denatured and then hybridized to a specific oligonucleotide primer. As the DNA polymerase extends the primer by incorporating bases (dNTPs) complementary to the template, it occasionally incorporates a terminator base analog (ddA, ddG, ddT, or ddC) that stops further extension. The result is a mixture of extended products with varying lengths. Each terminator base may be labeled with one of four different fuorescent tags (shown as symbols with different shapes [circles, triangles] and colors in the diagram). The original procedure incorporated a radioactive dNTP during extension, allowing monochromatic detection of the truncated fragments that were electrophoresed in four separate lanes, one lane for each of the terminator bases.

in HIV RNA that convey drug resistance and of HCV to identify mutations that af ect prognosis and influence the choice of therapy.

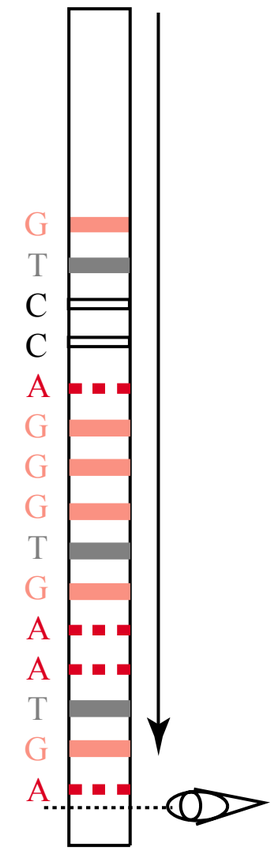
Single Nucleotide Extension

Single nucleotide extension (SNE) assays (also known as **single-base primer extension (SBE)** or minisequencing assays) are performed by annealing a primer to ssDNA immediately adjacent to the single base variant. T e primer is then extended by the polymerase with dideoxynucleotide terminators in the absence of dNTPs. Each of the four terminators is labeled with a unique label so that it is possible to identify the incorporated base. SNE assays have been multiplexed on automated DNA sequencing instruments by varying the lengths of the primers so that each SNV is resolved by size in one electrophoresis run. T ere are also many SNE detection methods other than electrophoresis, including (1) photometric detection on microtiter plates, (2) product-capture detection systems on **DNA microarrays**, (3) bead hybridization assays detected by **f ow cytometry**, (4) solution-based fluorescence polarization detection systems, and (5) mass spectrometry. SNE assays are useful when a moderate number of disease-causing SNVs need to be genotyped. T ey do not work well if there are polymorphisms in the primer-binding site. Also, they are not designed to detect variants at positions other than immediately adjacent to the primer.

Oligo Ligation

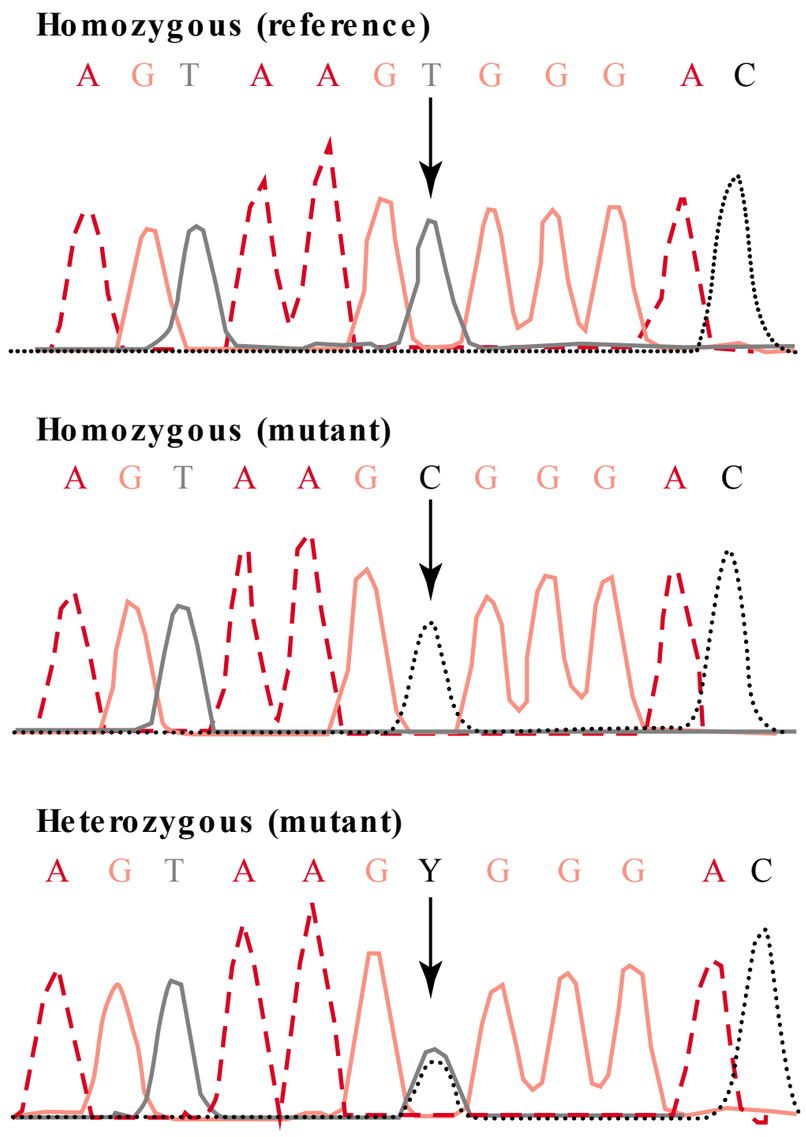
Another assay format for SNV detection is the **oligonucleotide ligation assay (OLA)**. With this assay, two oligonucleotide probes are hybridized to adjacent sequences of amplified target DNA with the known SNV site positioned at the end of one probe (Figure 48-13). DNA ligase covalently joins the two probes only if both are perfectly hybridized to the target. A probe matching the normal base and another probe matching the mutant base are usually prepared with dif erent length tails that modify their electrophoretic mobility. T e probe hybridizing to both alleles is fluorescently labeled. Multiplexing of SNV genotyping is achieved by attaching dif erent fluorescent labels to the common probes and also varying the tail lengths on the allele-specific probes. Following ligation, probes for multiple SNV sites are separated on a sequencing gel.

Multiplex Ligation-Dependent Probe Amplif cation



Muliplex ligation-dependent probe amplification (MLPA)[11] is a convenient method for relative quantification of 10 to 50 targets. T e method is particularly useful to screen for deletions or duplications of multiple exons within a gene. For each target, two probes are designed that hybridize adjacent to each other so that they are in position to be ligated. T e two probes have unique sequence tails that do not hybridize to the target and that are the same between targets. After hybridization and ligation, the probes are amplified by PCR with a common primer pair (complementary to the tails). One of the primers is fluorescently labeled at its 5′ end. Because probes of dif erent lengths are used, multiple PCR products of dif erent sizes are produced and separated on a sequencing gel. T e relative peak heights or areas of each target are compared for relative quantification.

Discrimination by Mass or Sequence without Electrophoresis



Newer technologies that replace assays traditionally performed by electrophoresis are emerging. Some of these are attractive alternatives for the clinical laboratory because they are amenable to automation. T ese approaches include (1) mass spectrometry, (2) pyrosequencing, and (3) high-throughput sequencing.

Mass Spectrometry

Matrix-assisted laser-desorption ionization time-of-flight (MALDI-TOF) mass spectrometry (see Chapter 13) is used to genotype sequence variants. With mass spectrometry, no

Four color sequencing

Automated sequencing read out

Figure 48-12 Schematic of targeted DNA sequencing. Extension products generated by the chain-termination reaction with different colors for each terminating base are separated by polyacrylamide gel electrophoresis. Automated fuorescence detection (shown by the eye icon) identifies each base during capillary electrophoresis. The direction of fragment migration is from top to bottom. The sequence is read from bottom to top in the gels and from left to right for the automated sequence. Examples of a reference sample (homozygous T at the polymorphic site), a mutant sample (homozygous C), and a heterozygous mutant sample (T and C) are shown. Y indicates a pyrimidine (T or C).

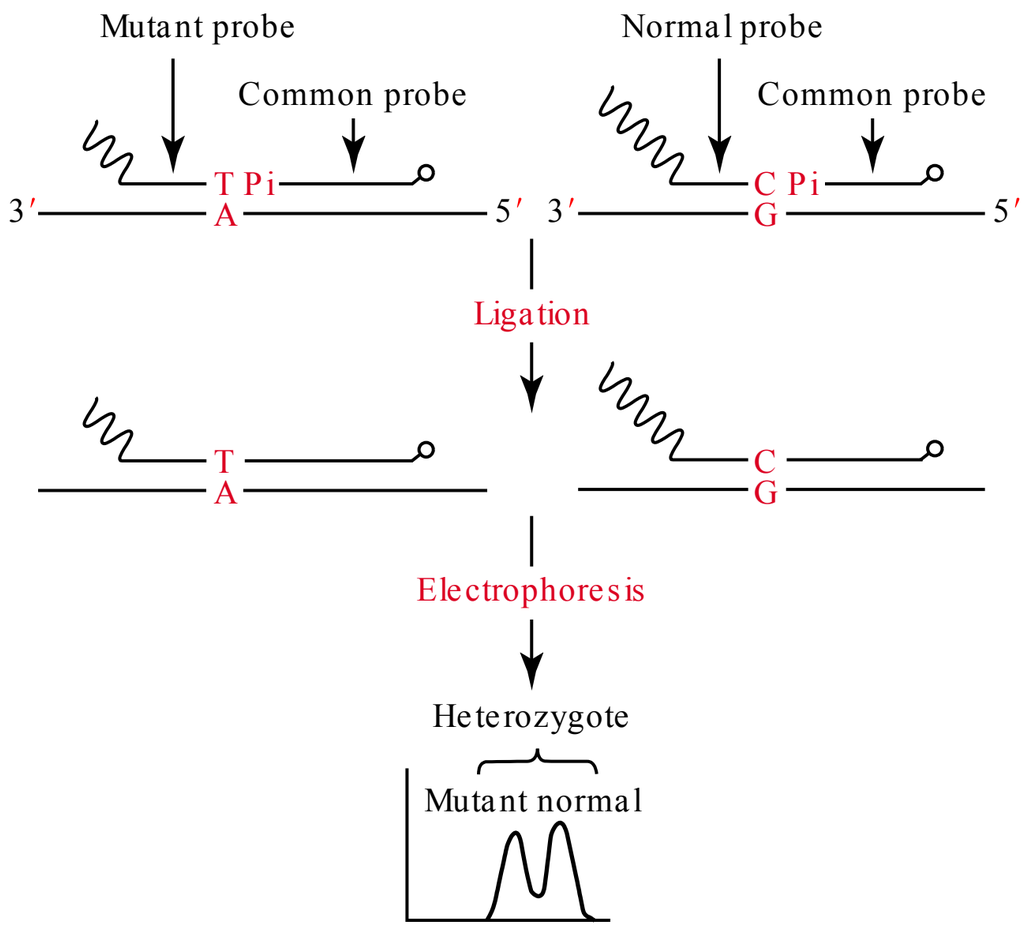


Figure 48-13 Oligo ligation assay (OLA). A probe specific to the normal allele (C) is shown hybridized onto a normal DNA sample (G). This probe also is attached to a mobility modifying tail. Hybridized next to the normal-allele probe is the common probe that is labeled with a fuorescent tag. In the presence of ligase, the two probes are covalently joined to generate a longer probe. The mutant-allele-specific probe (T) with a shorter tail also hybridizes to the normal DNA sample, but it is not ligated to the common probe because of the mismatched base at its 3′ end. Electrophoresis and end-point, laser-induced detection reveals the ligated normal-allele probe, which is differentiated from the significantly shorter common probe alone (not shown on the graph) or from a ligated mutant-allele probe because of the different lengths of their tails. Multiple single-nucleotide variant (SNV) sites can be analyzed in one electrophoresis assay by varying the tail lengths (e.g., SNV site 2 in the graph) or by use of multicolor fuorescence tags.

label is necessary, because the alleles dif er in mass. A DNA fragment including the variant site is amplified by PCR. After removal of the primers and dNTPs, an extension primer is hybridized directly or closely adjacent to the polymorphic site. Appropriate unlabeled deoxynucleotides and/or dideoxynucleotides are incorporated to generate allele-specific diagnostic products of dif erent masses. Salt is removed from the sample, and approximately 10 nL of it is spotted onto an array and the mass of the extension products used to determine the genotype (Figure 48-14). Despite its complexity, automated systems are available that are capable of processing 384 to 1536 samples in a batch.

Pyrosequencing

Pyrosequencing determines the nucleic acid sequence of short segments without electrophoresis. With this technique, a sequencing primer is first hybridized to a single-stranded template previously generated by PCR. Four enzymes and two substrates are included in the reaction mixture (Figure 48-15). Next, one of the four dNTPs is added. If the base is complementary to the template strand, DNA polymerase catalyzes its incorporation and releases pyrophosphate (PPi). PPi release generates visible light through linked enzyme reactions. T e process is repeated by adding one dNTP at a time to determine the nucleotide sequence. Because the technique has been automated, it is useful when the sequences of a large number of short segments need to be determined.

High Throughput Sequencing with Amplif cation

T e need to understand genome-wide human variation has led to the development of new high-throughput sequencing techniques.[13] Most of these techniques typically are initiated by randomly fragmenting DNA into small pieces, usually less than 1 kb, and many between 100 and 500 bases. Short adapter sequences are ligated to each fragment to provide priming sites that initiate massively parallel sequencing reactions. Adapters also facilitate initial capture of DNA fragments onto solid surfaces to spatially restrict clonal amplification onto beads or spots on an array surface. Clonal amplification is performed by one of several methods, including the following:

- Emulsion PCR, in which one strand of the template fragment is captured on one bead and clonally amplified inside a water-in-oil droplet, generating a bead tethered by single-stranded amplicons (Figure 48-16). T e beads are then deposited onto a glass surface or into discrete wells on a fiberoptic slide.
- Bridge amplification, which generates clusters of single-stranded amplicons tethered to the surface of a planar flowcell (Figure 48-17).[4]
- RCA, which generates concatemers (intermediate structures formed during the replication of some DNA molecules) of templates that self-assemble into DNA balls in solution and are deposited onto ordered spots on a silicon array.

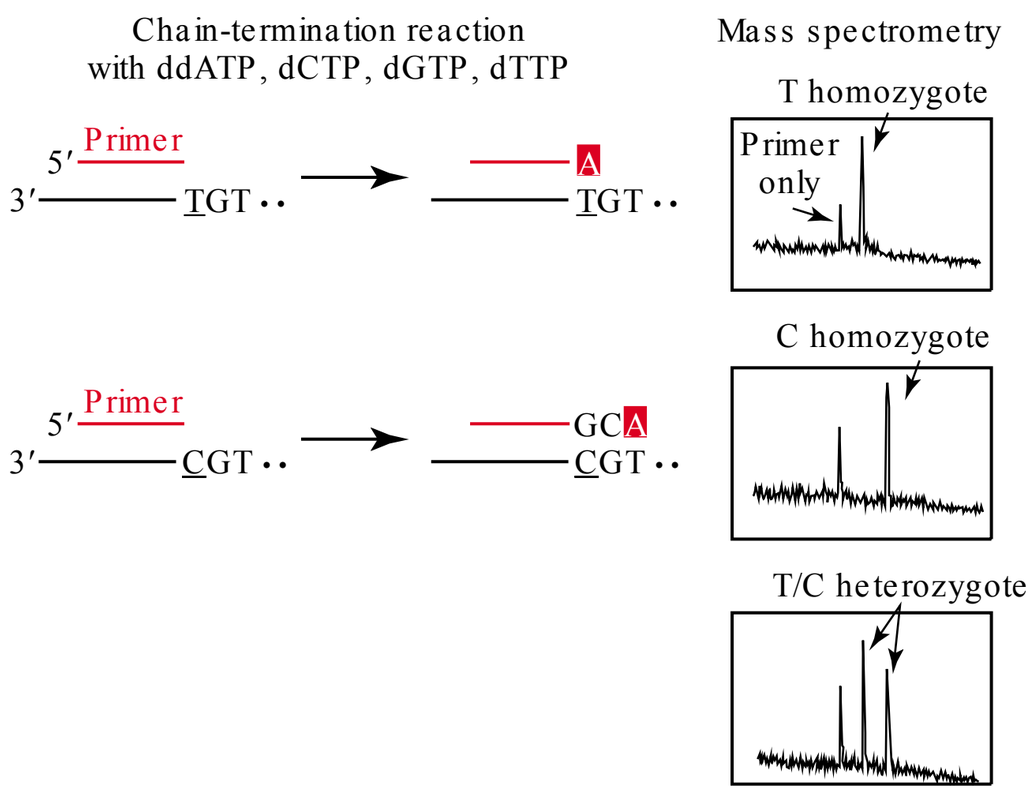

Figure 48-14 Sequence polymorphism analysis by mass spectrometry. The underlined base is the polymorphic site in the template (T or C). The single-stranded template is primed and extended in the presence of three dNTPs and one ddNTP, producing fragments of different mass depending on the sequence. The boxed "A" in this example indicates the incorporated terminator adenine base. The mass of terminated products is precisely measured by matrix-assisted laser-desorption ionization time-of-fight (MALDI-TOF) mass spectrometric data (relative intensity versus m/z).

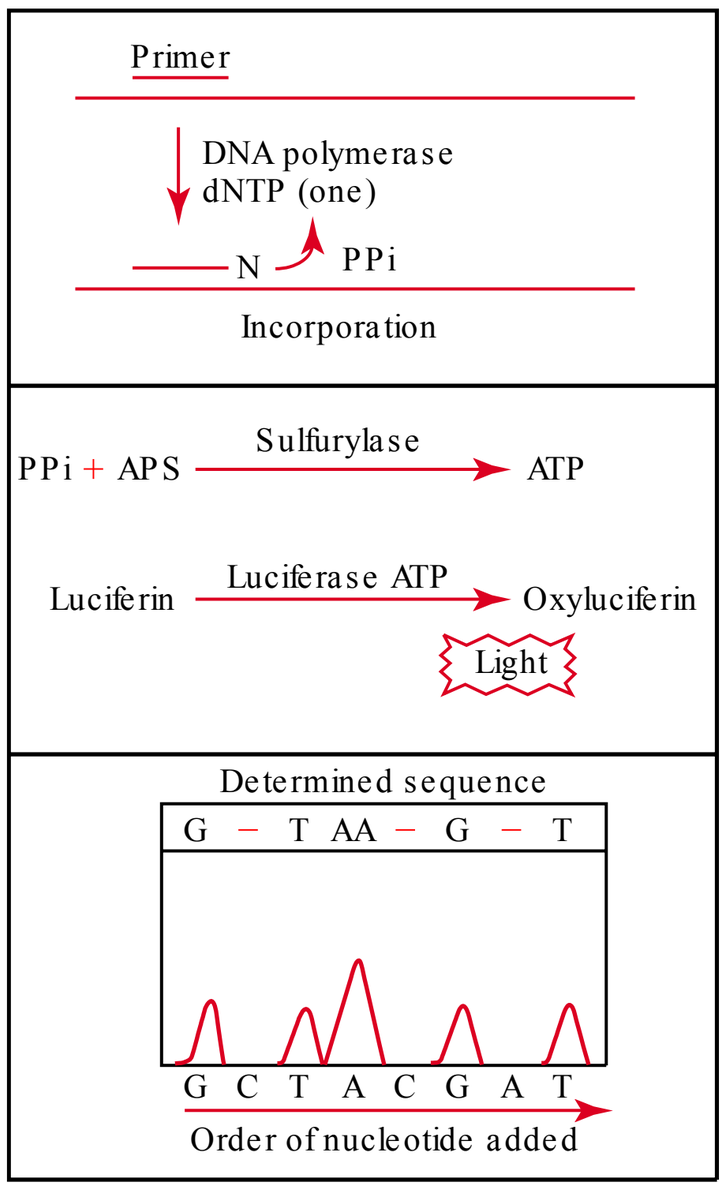

Figure 48-15 Schematic of pyrosequencing. Individual dNTPs are added one by one to the single-stranded template, a primer, and a polymerase. Pyrophosphate (PPi) is generated if the dNTP is complementary to the next base on the template (top). Any PPi produced reacts with adenosine-5′-phosphosulfate (APS) to produce ATP, which in turn generates light in the presence of luciferase (middle). The sequence can be determined from the order of dNTP addition and the intensity of light produced.

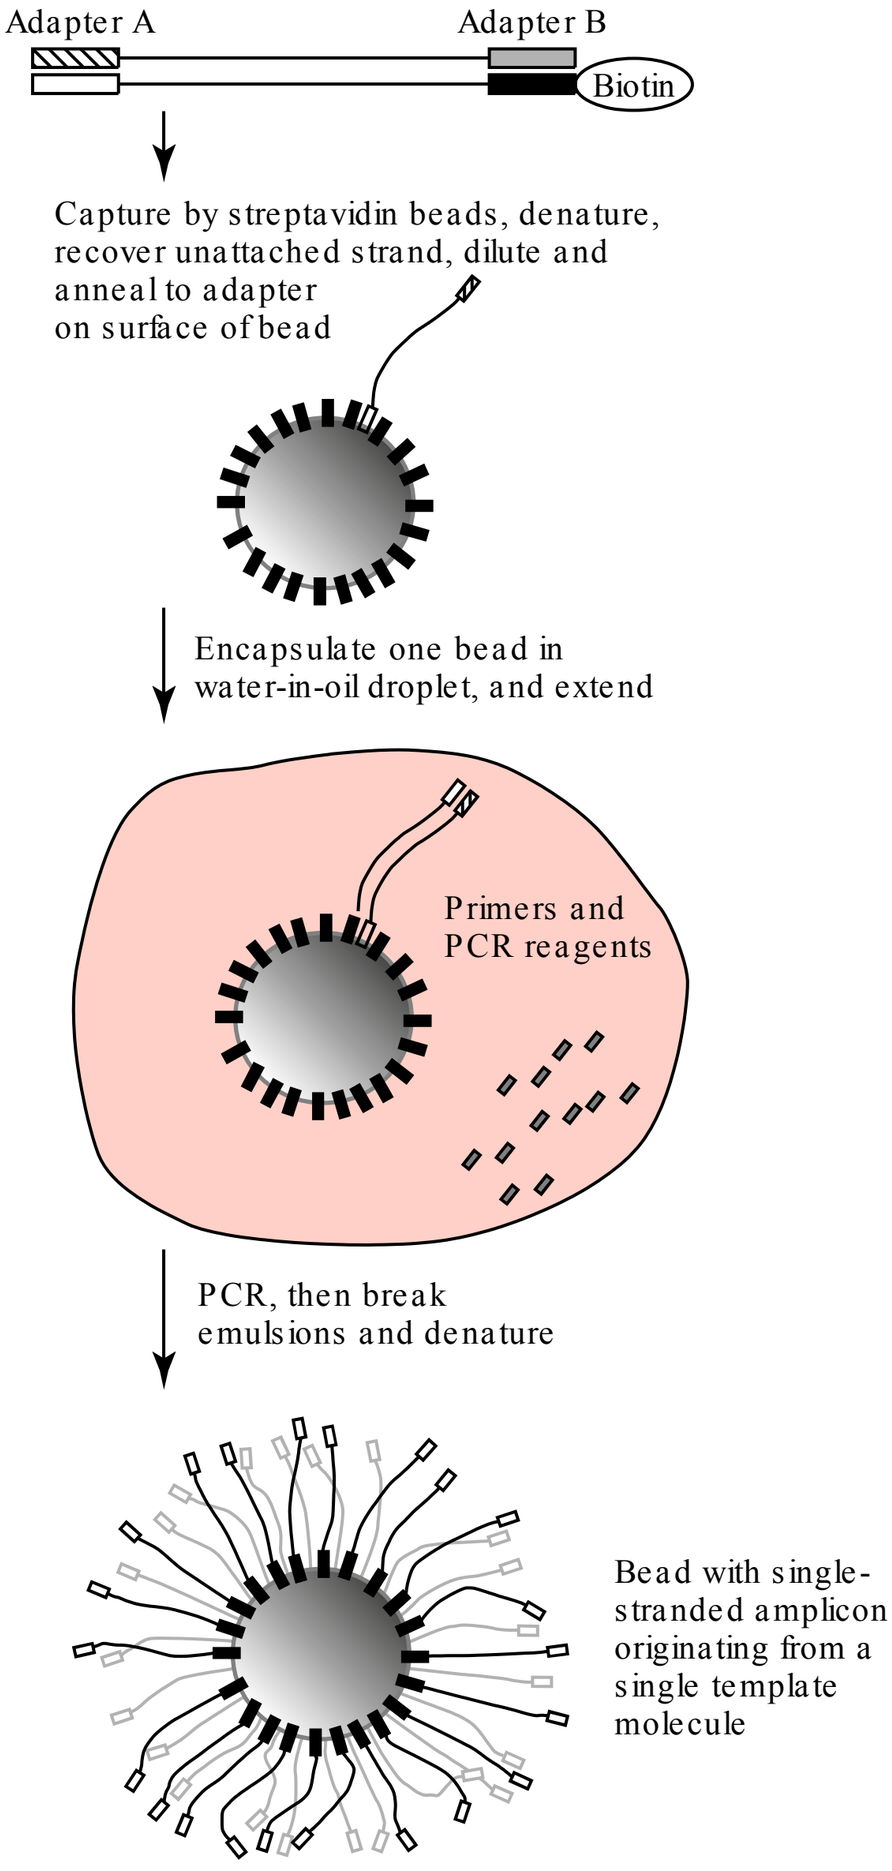

Figure 48-16 Emulsion polymerase chain reaction (PCR). Two adapters (adapters A and B) are randomly ligated to DNA fragments. Adapter B has a biotin on its 5′ end. Fragments with adapter B on one or both ends are captured by streptavidin beads, while fragments with only adapter A are washed away (not shown). Then fragments are denatured, and the free strand with adapter A and adapter B at each end is collected (fragments with adapter B on both ends will not be released from the streptavidin bead). One molecule of the single-stranded template is then captured on a bead coated with adapter and is encapsulated inside a water-in-oil droplet that contains PCR reagents and primers. After PCR, the emulsion is broken and the DNA is denatured. This generates a bead with a large number of clonal single strands tethered to it. The bead is then deposited into one of many wells on a fiberoptic slide, or onto a glass slide for sequence analysis (not shown).

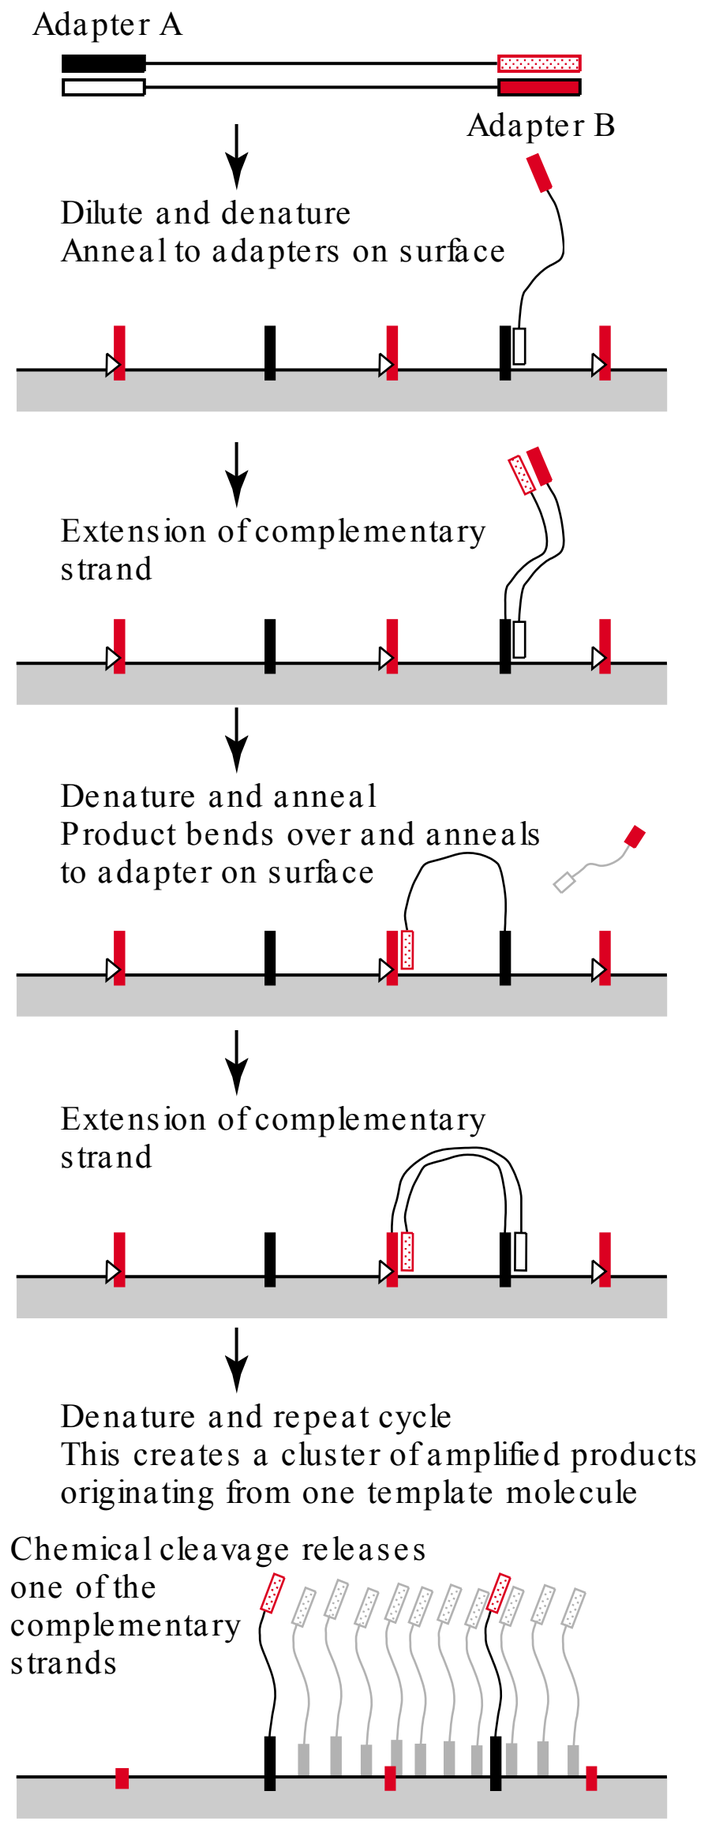

Figure 48-17 Bridge amplification. Two adapters (A and B) are ligated to a DNA template. Once diluted and denatured into single strands, the template is captured onto a flow cell surface by annealing to one of the two surface-bound primers that share sequences with adapter A or B. The polymerase reagent introduced into the flow cell extends the primer and generates the complementary strand of the template. The denaturant (usually sodium hydroxide) is introduced to the flow cell to release the original template strand. The free end of the newly synthesized strand anneals to a nearby primer by bending over, and a second round of reagent addition catalyzes the synthesis of another complementary strand. By repeating many of these cycles, a clonal cluster that consists of about 1000 copies of single-stranded template tethered to the surface is generated. This cluster is still a mixture of both complementary strands. One of the strands is selectively eliminated by treatment with periodic acid that cleaves the diol linkage present in one of the surface-bound primers (open triangle on red primer). The cluster now contains only one of the template strands and is ready for sequence analysis.

Sequence determination of nucleic acids is performed on these clonally amplified templates in a massively parallel fashion using sequencing by synthesis. In the presence of polymerase and a primer, one dNTP is added at a time and incorporation detected by pyrosequencing, fluorescence, or pH changes (semiconductor sequencing).

High-Throughput Sequencing without Amplification

Some high-throughput sequencing methods do not require amplification. With these techniques, sensitive optical techniques are used to observe incorporation of fluorescent nucleotides during strand synthesis on single template molecules. One such method observes real-time DNA synthesis by a single polymerase molecule immobilized inside a nanostructure array. The method uses four-color dNTPs whose label cleaves of as nucleotides are incorporated into the newly synthesized DNA strand. Each addition of a base is observed as a short pulse of one of the colors representing one of four bases. Long contiguous reads are possible. When high accuracy is achieved, single molecule methods have advantages of (1) efficient sequence assembly, (2) analyses of repetitive sequences, and (3) de novo sequencing. In contrast, many of the other high-throughput sequencing methods generate short sequence reads (30 to 70 bases long) that have to be aligned and analyzed to derive a consensus, then stitched together and compared with reference genome sequences. Accurate assembly of sequence data relies on sufficient coverage or redundancy across the sequenced region and informatics tools for this process are rapidly evolving.

Hybridization Assays

Principles

Hybridization assays are based on the ability of single-stranded nucleic acids to form specific double-stranded hybrids. The process requires that (1) probe and target nucleic acids are mixed under conditions that allow for complementary base pairing and (2) there is a method to detect any resulting double-stranded nucleic acids. A "probe" is a nucleic acid whose identity and sequence is known and is used to hybridize to a complementary target nucleic acid whose identity or abundance is revealed by the hybridization. In some of the methods discussed below, hybridization occurs between a target in solution and a probe that is attached ("tethered") to a solid surface. In homogeneous or real-time techniques, both the probes and the targets are in solution, and hybridization and detection occur without washing steps. Some of the homogeneous methods also monitor the dissociation of hybridized duplexes under controlled heating, revealing the identities of the hybridized duplexes by melting curve signatures.

As with any assay, both positive and negative controls are necessary for validation of the analytical phase of hybridization assays. Positive controls contain sequences complementary to the probe that are used to assess assay sensitivity, and they ensure that conditions are right for the probe to hybridize to the target under the assay conditions. Negative controls without target sequence assess assay specificity and will detect positive contamination if present.

Hybridization Thermodynamics

The favored structure of DNA under physiological conditions is an ordered double-stranded helix held together by noncovalent interactions (see Chapter 47). The duplex structure is most stable when all opposing bases are complementary, allowing for maximal hydrogen bonding and base stacking. The noncovalent binding between two DNA strands is (1) specific, (2) sequence dependent, and (3) reversible. Denaturing conditions, such as

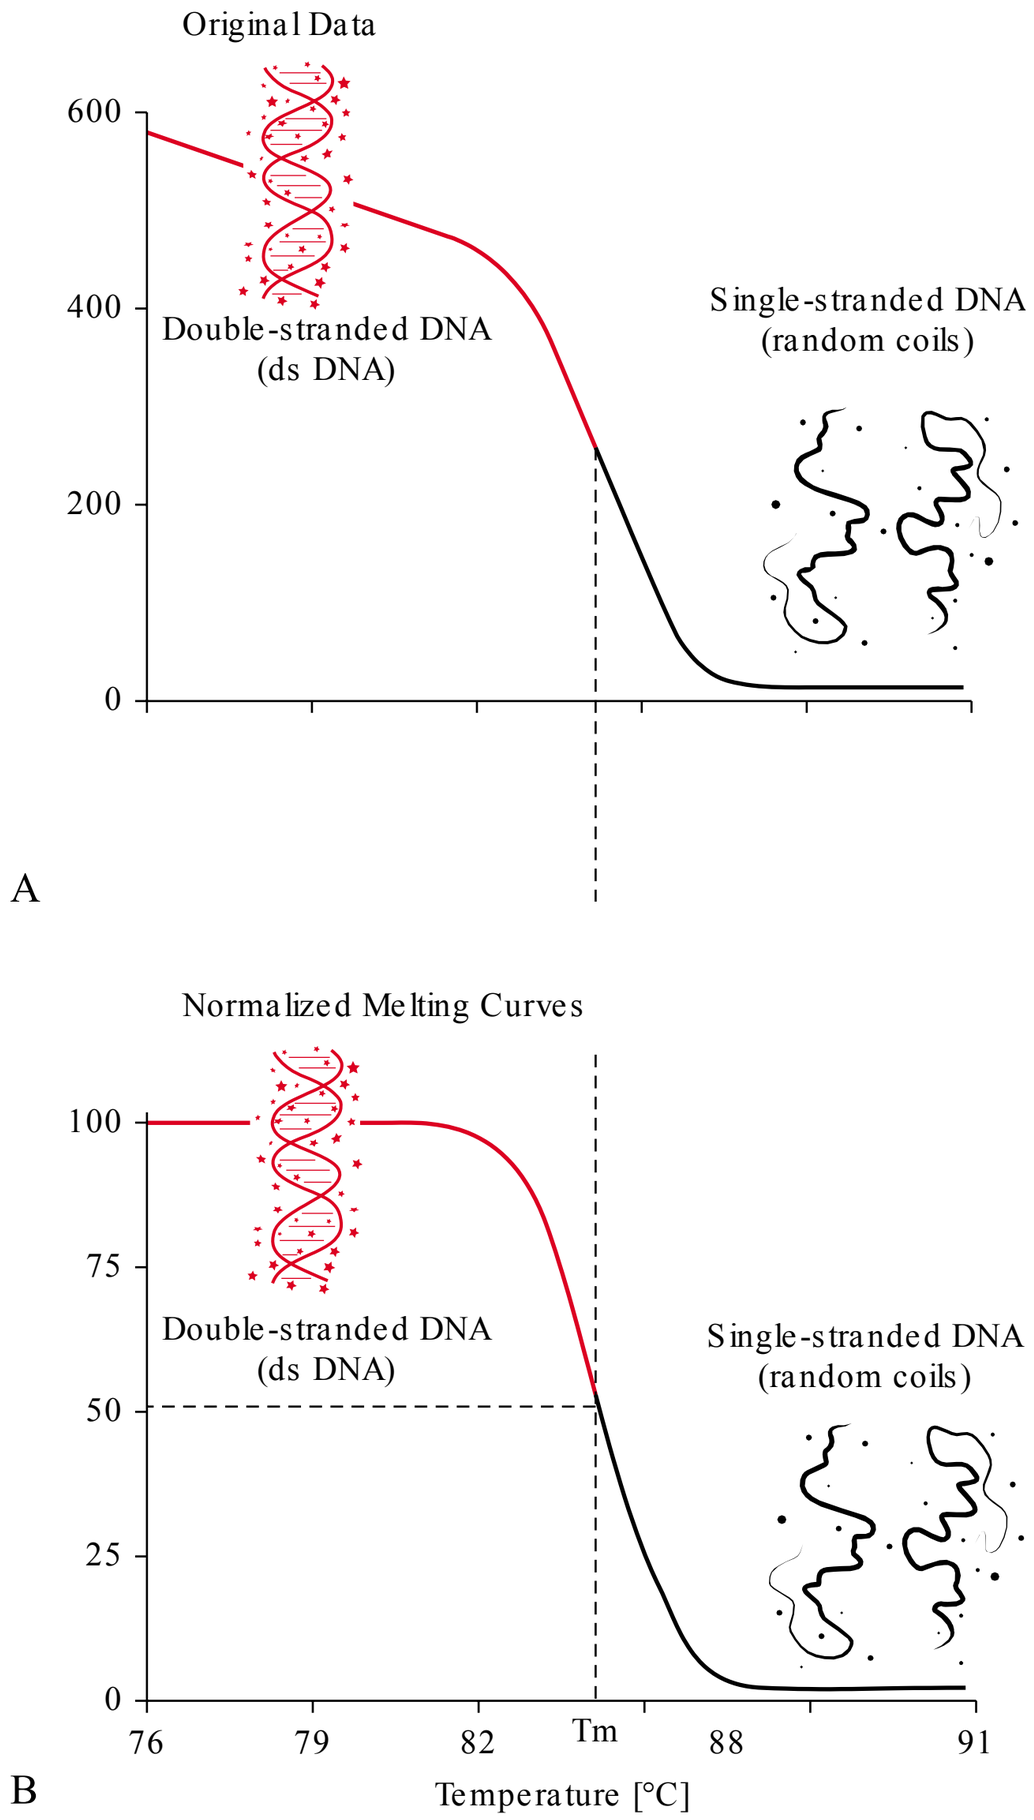

Figure 48-18 Fluorescence melting curve of a polymerase chain reaction (PCR) product. PCR-amplified DNA was melted in the presence of the cyanine dye, LCGreen Plus. In panel A, fuorescence gradually decreases as the temperature is increased until a more rapid decrease occurs centered at the DNA melting temperature (Tm) of the PCR product. In panel B, the data are normalized between 0% and 100% after removal of background fuorescence to obtain constant fuorescence outside of the transition. (Modified with permission of the publisher from Wittwer CT, Kusukawa N. Real-time PCR and melting analysis. In Persing DH, Tenover FC, Tang YW, et al, eds. Molecular microbiology: diagnostic principles and practice, 2nd edition, Washington, DC: ASM Press, 2011:63-82. © 2011 ASM Press.)

(1) high temperature (>90 °C), (2) presence of formamide, or (3) extremes of pH, favor dissociation of the double-stranded molecule into two separate random coils (Figure 48-18). On removal of the denaturant, single strands attempt to rejoin to form duplexes; rejoining strongly favors interactions that maximize complementary base pairing. Because temperature is the denaturant most easily manipulated, the **melting temperature** (T_m) of a DNA molecule is defined as the temperature at which 50% of the DNA molecules dissociate or "melt" from a double strand configuration to a single-strand configuration. Molecules with mismatched base pairs are less stable than those with a perfect sequence match and thus melt at a lower temperature. The reverse process, in which two complementary strands recombine to form a stable duplex molecule, is referred to as annealing or hybridization. Hybridization occurs between (1) DNA strands, (2) RNA strands, and (3) strands of **nucleic acid analogs** (such as **peptide nucleic acids [PNAs]**), in all combinations.

Hybridization Kinetics

The rate kinetics of solution-phase hybridizations is second order, being proportional to the concentrations of both hybridizing strands. The rate-limiting step is nucleation, where a small number of base pairs are formed in the correct orientation, followed by a rapid "zippering" of complementary sequences. In the case of a probe present in great excess to the target, hybridization proceeds as a pseudo–first order reaction, depending only on the concentration of the target. However, the time required to hybridize the probe to a given fraction of the target is proportional to the probe concentration. For example, during a PCR the concentration of primers is much greater than that of the target, and the reaction rate during each annealing step depends on the concentration of available single-stranded product, but the time required to anneal primers to a certain fraction of the target is proportional to the primer concentration.

The availability of nucleic acids for hybridization also is an issue. As the temperature cools during thermocycling, PCR primer annealing competes with the formation of double-stranded product. As the concentration of product increases during a PCR, some double-stranded product is formed before primer annealing occurs (see Figure 48-3). Similarly, when double-stranded probes are used at high concentrations, probe self-annealing interferes with probe-target hybridization. Available hybridization sites also are limited by intramolecular secondary structure of the probe or target, such as seen in SSCP.

Hybridization rates are influenced by many factors in the reaction environment, most notably temperature and ionic strength. Above the Tm, no stable hybrids are present, although transient complexes may form. As the temperature is lowered below the Tm, hybridization rates increase until a broad maximum occurs about 20 °C to 25 °C below the Tm. Hybridization rates also increase with an increase with the ionic strength of a solution. Divalent cations, such as Mg^{+2}, have a much stronger effect than monovalent cations, such as Na^{+} or K^{+}.

Probes

In a hybridization assay, the probe is analogous in its role and importance to the antibody in an immunoassay. As discussed earlier, a probe is the nucleic acid whose identity is known and is used to reveal the identity or abundance of a target. Like antibodies in immunoassays, probes are either unlabeled or labeled with one of a variety of reporter molecules. Probes may be (1) cloned (recombinant), (2) generated by PCR, or (3) synthesized (oligonucleotides). They may be (1) DNA, (2) RNA, or (3) PNA, and single stranded or double stranded. Selection, purification, and labeling of probes are crucial to success of hybridization assays.

Cloned Probes

Cloned probes consist of a known segment of DNA inserted into a **plasmid** vector that is propagated by growth in a bacterium. Many different plasmid vectors are now available; pBR322 was one of the first in common use. The entire plasmid DNA (insert plus vector sequences) may be used as a probe, or the insert may be purified first from the vector sequences. The latter method is obviously more cumbersome, but may result in reduced background. The resulting probe is a dsDNA probe, and it must be denatured before use.

Some vectors contain RNA promoter regions adjacent to the inserted DNA sequence. These regions permit generation of RNA transcripts from the DNA insert. Because only one strand is copied during the RNA synthesis, single-stranded RNA probes are generated. Controlling the orientation of the insert in relation to the promoter region allows the production of transcripts in the "sense" direction (same as mRNA) or "antisense" direction (complementary to mRNA).

Polymerase Chain Reaction-Generated Probes

PCR-generated probes are simple to prepare. During amplification, the PCR product typically is labeled with nucleotides that are (1) radioactive, (2) fluorescent, or (3) have attached affinity labels. If desired, single-stranded probes are obtained by using a biotin-labeled primer, followed by solid-phase separation with streptavidin.

Oligonucleotide Probes

Oligonucleotide probes are even easier to synthesize or acquire than PCR-generated probes. These probes are usually 15 to 45 bases of single-stranded nucleic acid that are chemically synthesized as a specific base sequence. Most commonly, they are DNA, but RNA and PNA oligonucleotides also are used. Methods of synthesis that are (1) automated, (2) efficient, and (3) accurate continue to lower the cost of producing probes. Sequence information is now routinely available in public databases, such as the National Institutes of Health (NIH) genetic sequence database GenBank[1], and a similarity check for probe sequence is performed using public algorithms, such as the Basic Local Alignment Search Tool (BLAST; http://blast.ncbi.nlm.nih.gov/;accessed December 30, 2013). In practice, probe sequences must be carefully chosen to minimize cross-hybridization with pseudogenes (eukaryotes) or related species (bacteria and viruses). The Tm of the probe should allow both favorable hybrid stability and discrimination between related sequences. Oligonucleotide probes are often prepared with covalent attachment of a reporter molecule (such as fluorescent dyes) or affinity labels that allow them to be attached to

solid supports. Probes used in real-time PCR are usually oligonucleotides with a fluorescent label.

Estimating Melting Temperature of Oligonucleotide Probes

Nearest-neighbor stability calculations allow probe Tm estimation to within 2 °C. A unified thermodynamic database has been compiled, and new parameters for all possible single mismatches and dangling ends have been estimated. Many software programs and websites are available to estimate Tm by computer simulation.[14]

Purity of Labeled Oligonucleotide Probes

The purity of labeled oligonucleotide probes is important for hybridization assays and critical in real-time PCR. Commercial oligonucleotides with a fluorescent label are of variable quality, and their concentration and purity should be assessed before use. Mass spectrometry and/or co-elution of absorbance at 260 nm (A_{260}) and fluorescence peaks on reversed-phase HPLC also are indicative of probe purity.

Quantitative estimates of probe purity are also obtained by simple absorbance measurements of fluorophore and the oligonucleotide and use of their molar absorptivities. The ratio of the concentrations of fluorophore and oligonucleotide should be nearly 1.0. Acceptable ratios are between 0.8 and 1.2. Ratios less than 0.8 suggest incomplete labeling or destruction of the attached dye. Ratios greater than 1.2 suggest the presence of free dye. Note, however, that a ratio near 1 is a necessary but not a sufficient criterion of a pure probe.

Hybridization Assays: Examples

Hybridization reactions are divided into two broad categories: (1) solid-phase, in which either probe or target is tethered to a solid support while the other is in solution, and (2) solution-phase, in which both are in solution (Table 48-3).

Solid-Phase Hybridization Assays

Solid-phase assays are of particular utility as multiple samples are processed together, which facilitates (1) control, (2) washing, and (3) separation procedures. Hybridization on a solid support is, however, less efficient than solution-hybridization, and the kinetics are slower and more difficult to predict. Both solid-phase and liquid-phase assays are used routinely in the clinical laboratory. Solid-phase assays include (1) dot blot assays, (2) line probe assays, (3) assays using arrays, (4) in situ hybridization assays, (5) **Southern blot** assays and (6) **Northern blot** assays.

TABLE 48-3 Hybridization Assays

Solid-Phase Hybridization	• Dot-blot and line-probe assays • Arrays (microarrays and medium-density arrays) • In situ hybridization • Southern and Northern blotting
Solution-Phase Hybridization	• Real-time PCR • PCR melting analysis • Single molecule visualization • Other classical techniques

Dot-Blot and Line-Probe Assays

Conventional hybridization assays on membranes are known as dot blots or line probes, depending on the geometry of the individual spots. The nucleic acids are applied with suction, forming a shape that is either round (dot) or elongated (line or slot). After immobilization the membrane is incubated with complementary nucleic acid at a constant temperature, followed by one or more washes to discriminate matched from mismatched nucleic acid. The method allows multiple simultaneous hybridizations under identical conditions.

Two general formats are used for these assays. In one, multiple samples are affixed to the solid support and interrogated by a small number of probes ("sample-down"). In the other, multiple probes are attached to the support and a small number of samples are added ("probe-down"). Results of dot-blot and line-probe assays are usually qualitative: if hybridization has occurred, a signal is generated at the specified spot and a simple yes or no interpretation is given.

Medium-Density Arrays

Dot-blot and line-probe assays have largely been replaced by medium-density arrays that typically analyze 20 to 500 spots. Medium-density arrays are useful for testing multiple mutations in specimens for (1) genetic disease, (2) oncology, and (3) pharmacogenetics. These arrays do not need to be attached to a two-dimensional surface as long as their location or "address" is able to be decoded. For example, microspheres can be used with flow cytometers, with the microspheres analogous to the spots on a two-dimensional surface. The microspheres can be coded by fluorescence intensity of dyes within them (which are detected by "channels" in the flow cytometer) while fluorescence in another channel monitors hybridization. All channels are then read simultaneously using a flow cytometer.

Microarrays

Increasing further the density of hybridization assays, microarrays (also called DNA arrays, DNA chips, or biochips) were introduced in the mid-1990s.[10] Compared with medium density arrays, spot sizes in microarrays are decreased (typically to less than 200 microns in diameter) such that one array contains thousands to millions of spots. This dimensional change requires specialized (1) detection equipment, (2) software, and (3) informatics to analyze the data. Because of their high density, microarrays have attracted intense interest among researchers who wish to monitor the whole genome for (1) **single-nucleotide variants (SNVs)** (2) gene expression, and (3) **copy number variants (CNVs)**.

Because SNVs represent the most common genetic difference between individuals, much effort has focused on correlating SNV genotypes to phenotype and disease association. Microarrays that analyze human SNVs (SNV chips) provide the technology to genotype most known human SNVs in one experiment. Nearby SNV alleles tend to cluster together as haplotypes, so disease association by haplotype simplifies the analysis.

Gene expression microarrays quantify the relative amounts of different mRNAs in test and reference samples. An example of a two-color microarray for gene expression is shown in Figure 48-19. Because the human genome is completely sequenced, mRNA probes are usually directly synthesized on microarrays. Modern gene expression arrays have been used to measure the mRNA transcribed from all human genes in one experiment.[15] They have been applied to almost every conceivable human condition, including (1) neoplastic, (2) inflammatory, and (3) psychiatric conditions. In oncology, gene expression microarrays have led to new diagnostic and prognostic markers in (1) breast cancer, (2) bladder cancer, (3) leukemia, and (4) sarcoma, among others.[14] Currently in the clinical laboratory, expression arrays are used directly in only a limited number of diagnostic or prognostic tests. Most arrays are used in marker discovery projects and for selection of a smaller panel of expression targets that are then analyzed by other quantitative methods (such as real-time PCR) that provides greater precision and dynamic range.

Another important clinical application of microarrays is the genome-wide analysis of deletions and duplications, referred to as copy number variants. CNV analysis using microarrays is replacing much of the traditional cytogenetic chromosome analysis (karyotyping) and **fluorescence in situ hybridization (FISH)** analysis. Similar to gene expression arrays, many of the CNV arrays use two-color comparative hybridization to determine the gene dosage in a specimen compared with a normal reference genome by the technique of **comparative genomic hybridization (CGH)**. Arrays for CGH use oligonucleotide probes for very high resolution and data density. An example

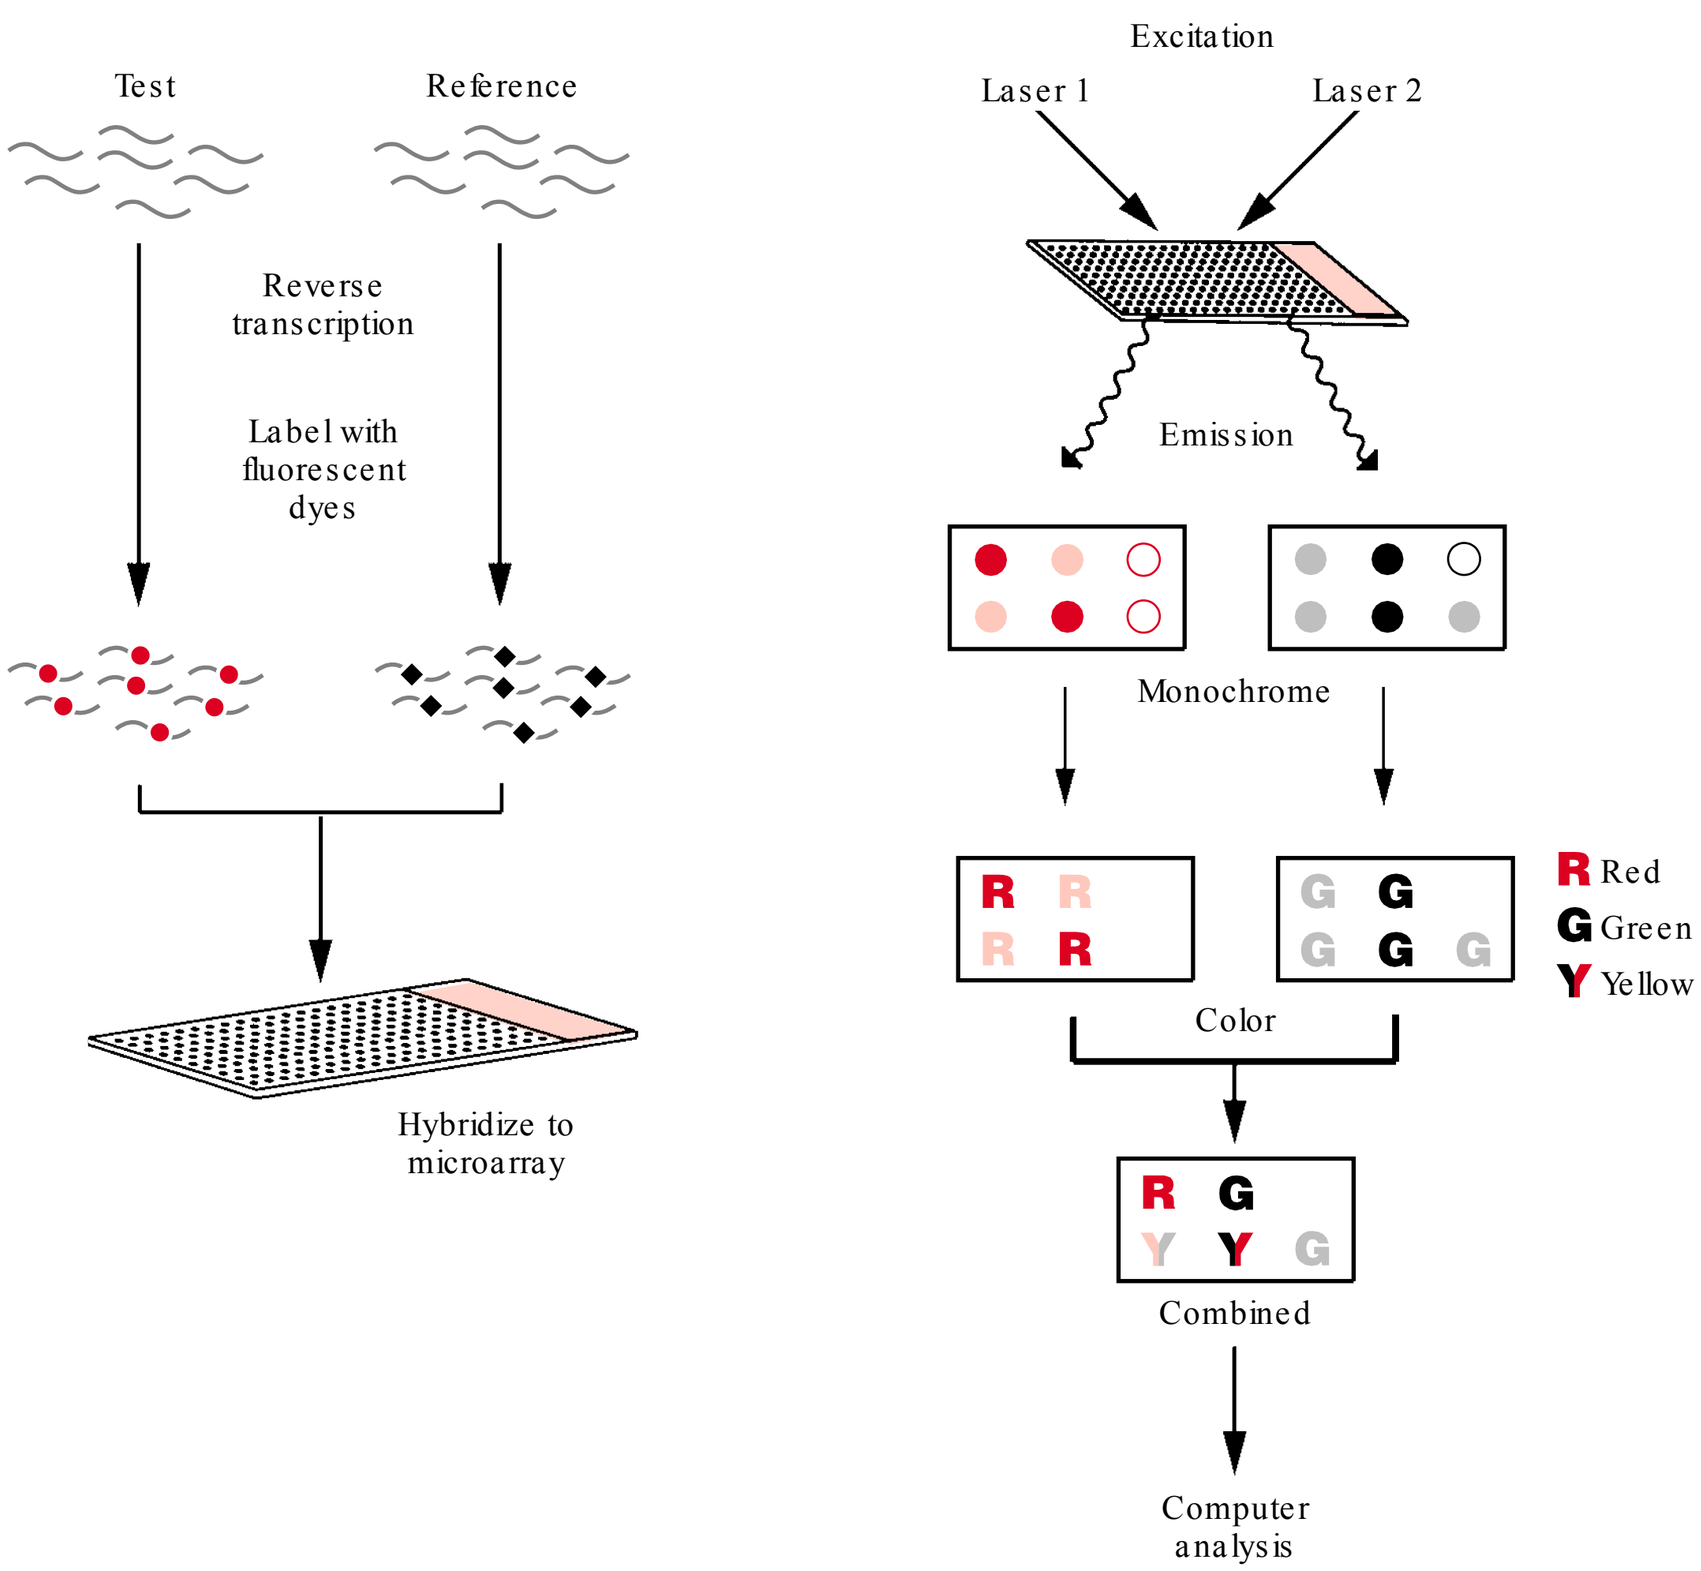

Figure 48-19 A two-color microarray experiment. An array of DNA oligonucleotides complementary to messenger RNA (mRNA) sequences is affixed to a glass slide. The mRNAs in the test and reference specimen are converted into differentially labeled cDNA by reverse transcription and incorporation of two different fluorescent dyes. The two samples are hybridized together onto the array. The array is washed, and the image is captured twice, each time with a laser of a wavelength that excites one of the dyes but not the other. The monochromatic images are then converted to two colors (green for the test sample [G], and red for the reference [R]), and the images are combined. If the abundance of cDNA is the same in each of the two samples, then the composite spot will be shown as yellow (Y). If one is in greater abundance, then that color will be preserved. Up-regulation and down-regulation of gene expression are then analyzed by software.

of CNV analysis using a CGH array is shown in Figure 48-20. SNV arrays also are used to detect copy number changes by loss of heterozygosity (this method is sometimes referred to as **virtual karyotyping**). Unlike CGH, SNV arrays have the advantage of analyzing the specimen without the need to mix in a reference genome. SNV arrays also are able to detect copy number neutral changes caused by inversions or uniparental disomy (a chromosome abnormality in which both chromosomes in a pair are inherited from the same parent) that are not detected by CGH methods.

Solution-Phase Hybridization Assays

Several classical hybridization methods use probe-target hybridization in solution. For example, hybrid capture employs an antibody that is specific for RNA-DNA hybrid molecules that are formed during solution-phase hybridization of a DNA sample and an unlabeled RNA probe. The assay also has been adapted to a **microtiter plate** format for automation of washing and detection. In addition, solution hybridization has been combined with (1) amplification, (2) detection, and (3) quantification steps all in the same tube. Such closed-tube, real-time assays do not require any additions, washing, or separation steps.

Single-Copy Visualization

If a nucleic acid probe is labeled with many fluorescent molecules, it is possible to optically visualize a single copy of a nucleic acid target by fluorescent microscopy. One technique

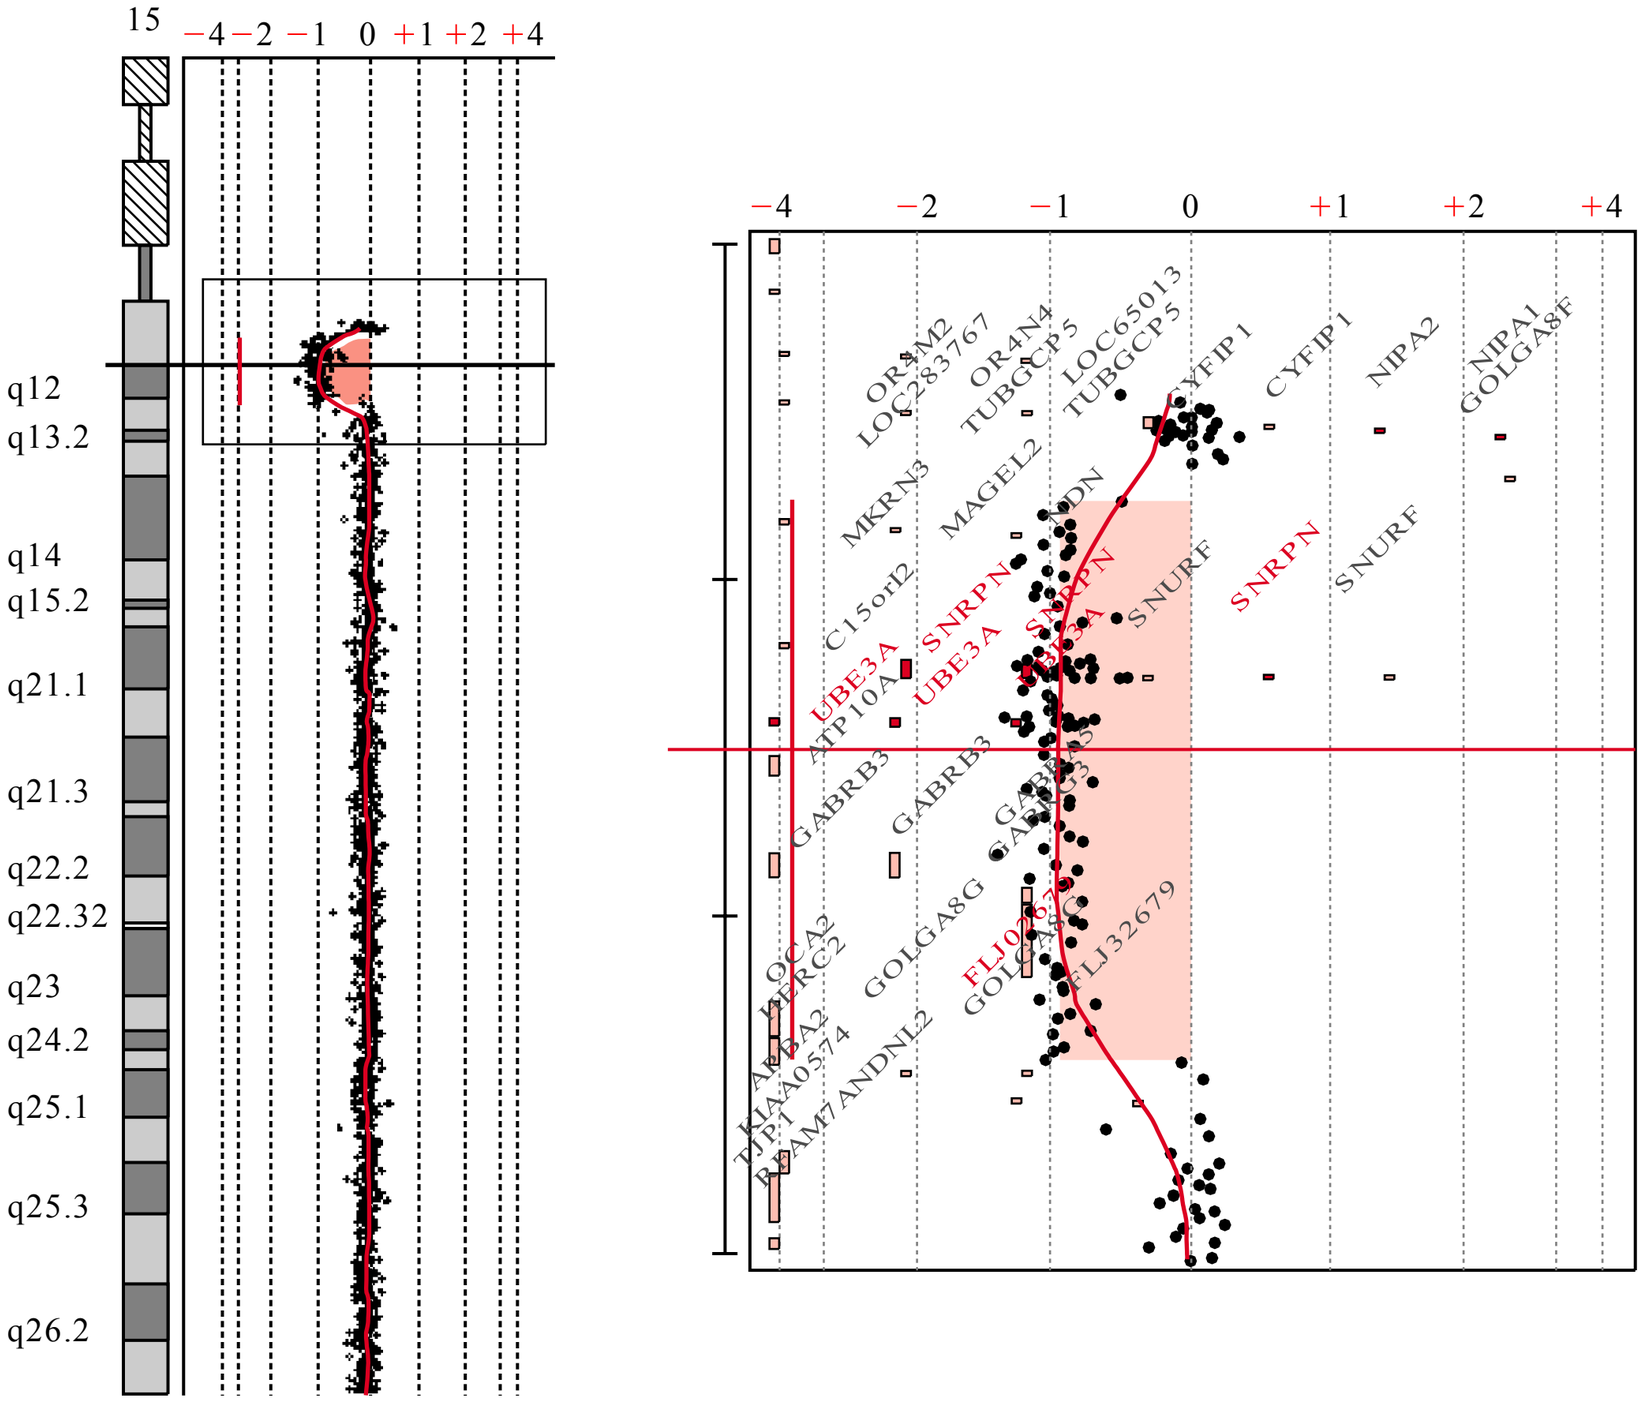

Figure 48-20 Copy number variation identified with a comparative genomic hybridization (CGH) array made from oligonucleotides. DNA from a subject is fragmented, labeled with Cy5, and hybridized onto a microarray, together with Cy3-labeled reference DNA. On the array are nearly 44,000 oligonucleotide probes, each about 60 bases long and tiled across the whole genome at an average spacing of 75 kb. The left panel shows results of probes on chromosome 15 (all other chromosomes are analyzed in this assay but are not shown). Each dot represents a specific probe to which the subject's DNA hybridizes. Their positions (0, −1, +1, etc.) reflect the dosage of the subject's DNA relative to the reference DNA. A majority of the probes line up on "0," indicating no quantitative difference compared with the reference DNA. Probes in the 15q11 to 15q13 region, however, are on the "−1" line, indicating that the subject has a deletion of that region in one of the chromosomes. A closer view of that region (right panel) shows that among the deleted genes are UBE3A, which causes Angelman syndrome, and SNRPN, which causes Prader-Willi syndrome. Because the method does not distinguish the methylation status of the deleted alleles, this result alone cannot determine which of the two disorders the subject has. (Courtesy Sarah South, Ph.D., ARUP Laboratories.)

uses reporter probes that are labeled with a long string of multicolored fluorescent labels. Several tandem color segments have been placed on the reporter probe with each segment consisting of about a hundred fluorophores. The sequence of different color segments uniquely identifies the target. The target nucleic acid is hybridized in solution with the reporter probe together with a capture probe and is (1) washed, (2) immobilized, (3) stretched, and (4) oriented on the surface of an optical slide. Each captured target is then identified by the color code of the reporter and is counted (Figure 48-21). Although the sensitivity of this technique is not as high as that of real-time PCR (see next section), up to 150 reporter probes have been multiplexed in one reaction. One application of this technique is direct measurement of mRNA expression in tissue specimens prepared from formalin-fixed paraffin blocks without the need for cDNA preparation or PCR.

Real-Time Polymerase Chain Reaction

Real-time PCR and melting analysis are considered "dynamic" hybridization assays in which the formation or dissociation of the probe-target duplex (or product duplex) is monitored in real time. With this technique, data elements are collected during the nucleic acid amplification step rather than at the end of it. The technique uses fluorescent dyes or probes and instrumentation that records fluorescence during thermal cycling. The data obtained provide information on the identity and quantity of the nucleic acid sample. During the entire process, the same reaction tube is used for amplification and fluorescence monitoring, and there are no (1) sample transfers, (2) reagent additions, or (3) gel separation steps required. This eliminates the risk of product contamination in subsequent reactions. Because the process is simple and fast, real-time PCR is replacing many older molecular techniques in the clinical laboratory.

Real-time PCR was first described using ethidium bromide to monitor the accumulation of a double-stranded PCR product.[2] If target DNA is present, the fluorescence signal increases. How early during PCR one begins to see a signal depends on the initial amount of target DNA, and this provides a systematic method of quantification. Further, when fluorescence is continuously monitored as the temperature is increased, a melting curve is generated. Often the first derivative of this melting curve is plotted to visually aid the analyst in determining the position of the Tm. Melting analysis is used to verify the identity of the amplified product and to detect sequence variants down to a single base (Figure 48-22).

Dyes and Probes for Real-Time Polymerase Chain Reaction

Many different fluorescent reporters are used in real-time PCR, and some of the more common ones are shown in Figure 48-23. Fluorescent probes have sequences complementary to the target, whereas dsDNA dyes and fluorescently-labeled primers rely on the specificity of the PCR primers. Some

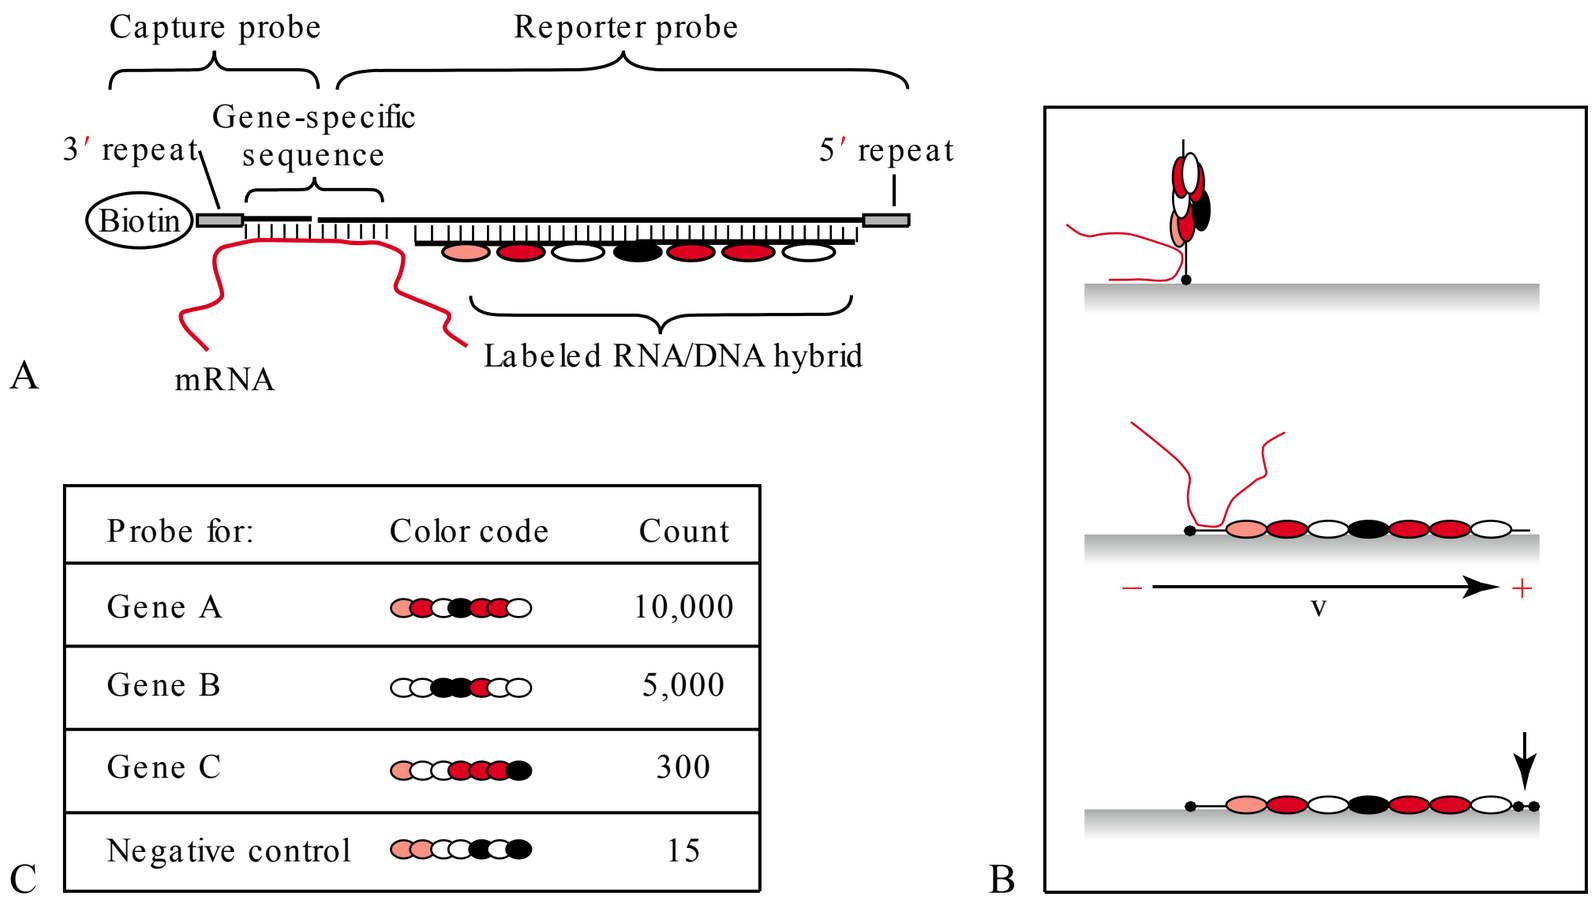

Figure 48-21 Single-copy visualization. A pair of probes (capture probe and reporter probe) hybridize to the messenger RNA (mRNA) target in solution through gene-specific probe sequences (A). The reporter probe has seven color segments, each segment made of ≈900 RNA bases that are labeled with about a hundred fuorophores of one color. The labeled portion of the probe is a DNA/RNA hybrid that can be observed as a ≈3 nm fuorescent spot. Excess probes and unbound DNA are removed and the target complex is immobilized on a streptavidin-coated slide through the biotin on the capture probe (B, top). An electrical current is applied, and the complex is stretched (B, middle). The reporter probe is immobilized in extended form by biotin-labeled oligonucleotides complementary to its 5′ repeat sequence (B, bottom). The color code of the probe is read by an epi-fuorescent microscope (a microscope where excitation of the fuorophore and detection of fuorescence are accomplished through the same light path), and each unique probe is counted (C). Normally, a number of negative control probes are present in the hybridization solution to establish nonspecific background counts.

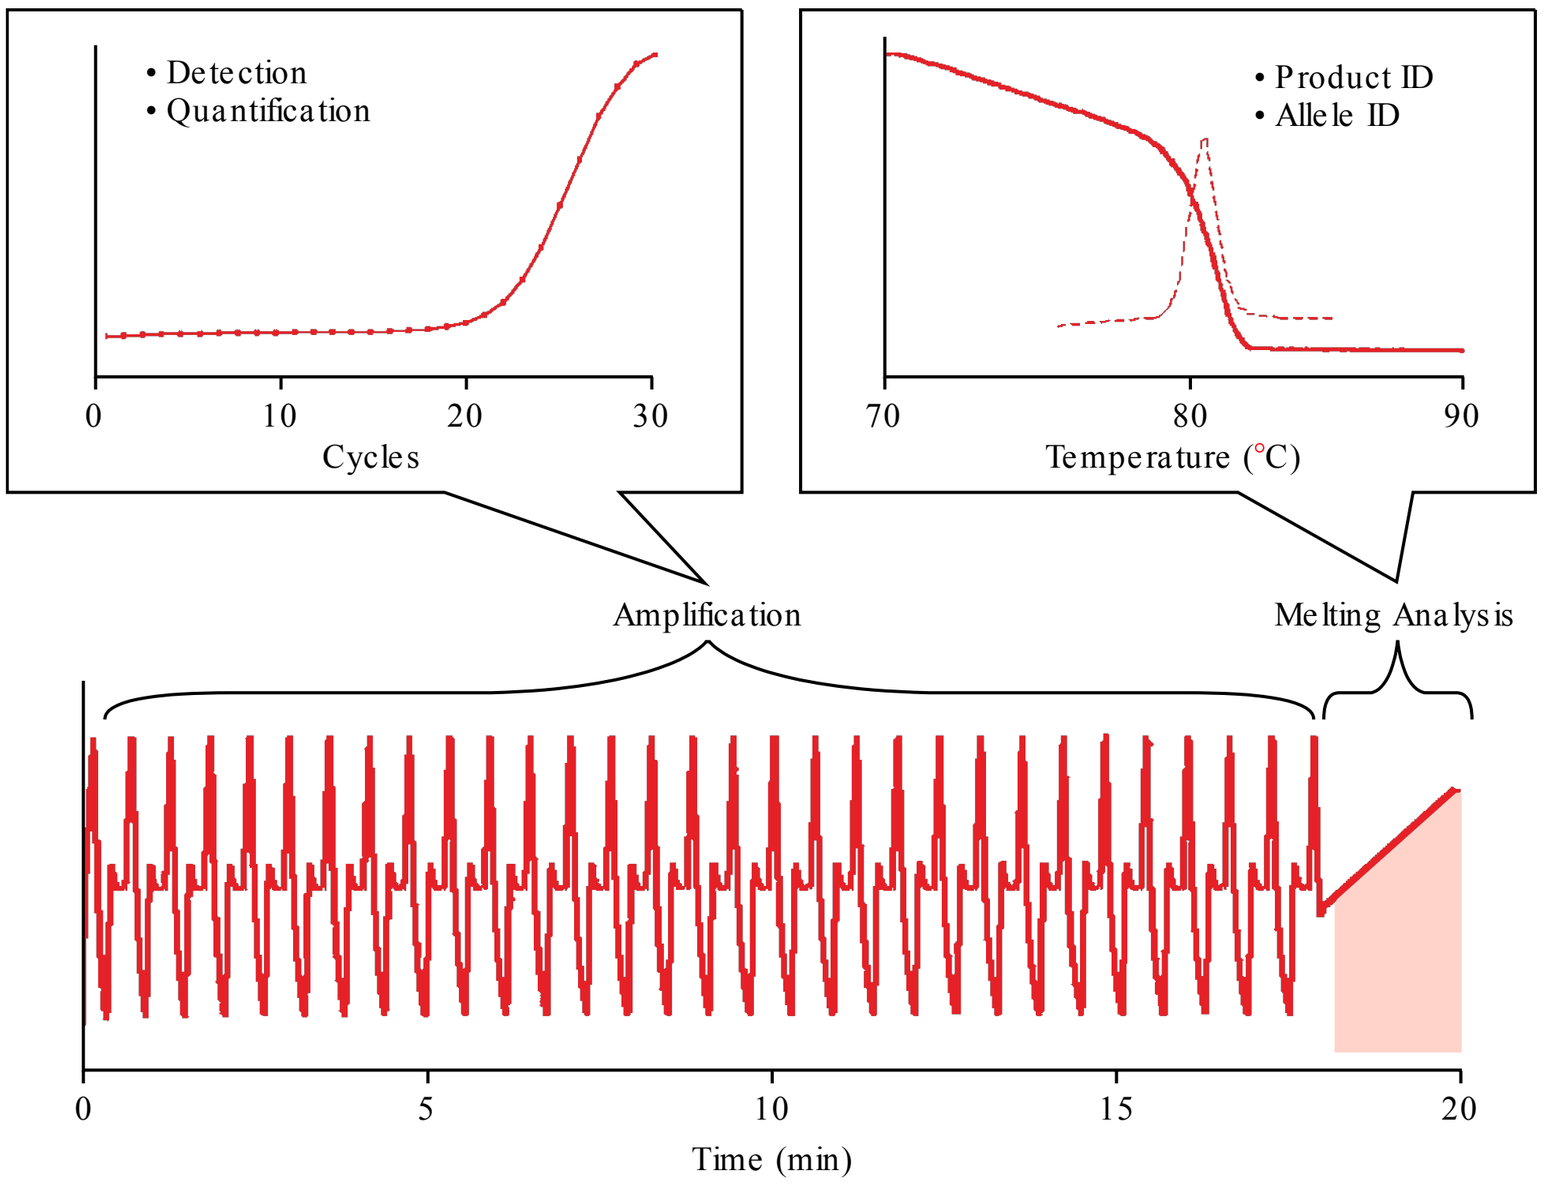

Figure 48-22 Real-time monitoring during amplif cation and melting analysis. The bottom panel shows a typical rapid-cycle temperature profile that is followed by a temperature ramp for melting analysis. When fuorescence is monitored during amplification once each cycle (dotted lines), information is provided on the presence or absence of specific target sequences and allows quantification of the target. When fuorescence is monitored continuously through the melting phase (shaded area), information can be provided that verifies target identification or establishes genotype. (Modifed with permission of the publisher from Wittwer CT, Kusukawa N. Real-time PCR. In: Persing DH, Tenover FC, Versalovic J, et al, eds. Molecular microbiology: diagnostic principles and practice. Washington, DC: ASM Press, 2004:71-84.)

methods include the option of melting analysis to verify the Tm of the probe or product.

Double-Stranded DNA Binding Dyes

Certain dyes increase their fluorescence in the presence of double-stranded DNA (ds-DNA) (see Figure 48-23, row one). Currently, SYBR Green I is the most common dye used in real-time PCR. It is popular in the research setting when the specificity of a probe is not needed, and the lower cost is attractive. T e dsDNA dyes also allow melting analysis at the end of PCR for product identification and some dyes even allow SNV genotyping by **high-resolution melting analysis (HRMA)** of PCR products.

Fluorescently Labeled Primers

Labeled primers also are used to monitor PCR. In one system, a primer with a 5′ hairpin is labeled with a fluorophore and a quencher so that fluorescence is quenched in the hairpin conformation. When the primer straightens out during the PCR process, fluorescence increases (see Figure 48-23, row six). One advantage of fluorescently labeled primers over dsDNA dyes is that multiplexing by color is possible. However, with both dsDNA dyes and labeled primers, reaction specificity depends completely on the primers. Any double-stranded product that is formed will be detected. T erefore, methods that increase specificity, such as **melting curve analysis**, are helpful to confirm the presence of the desired product.

Probe-Specif c Detection

T e use of fluorescent probes in PCR provides an additional level of specificity. Fluorescent probes that hybridize to PCR products during amplification change fluorescence by two possible mechanisms: (1) a covalent bond between two dyes is broken by hydrolysis, or (2) the fluorescence change follows reversible hybridization of the probe to the target. Following this distinction, when covalent bonds are broken, the probes are called hydrolysis probes. When probes reversibly change fluorescence on duplex formation, they are called hybridization probes. One major dif erence between the two probe types is that melting analysis is possible with hybridization probes, but not with hydrolysis probes.

Hybridization Probes. T ese probes change fluorescence upon hybridization, usually by FRET. Two interacting fluorophores may be placed on adjacent probes (see Figure 48-23, row two), or one may be placed on a primer and the other on a probe (see Figure 48-23, row three). Only one probe with one

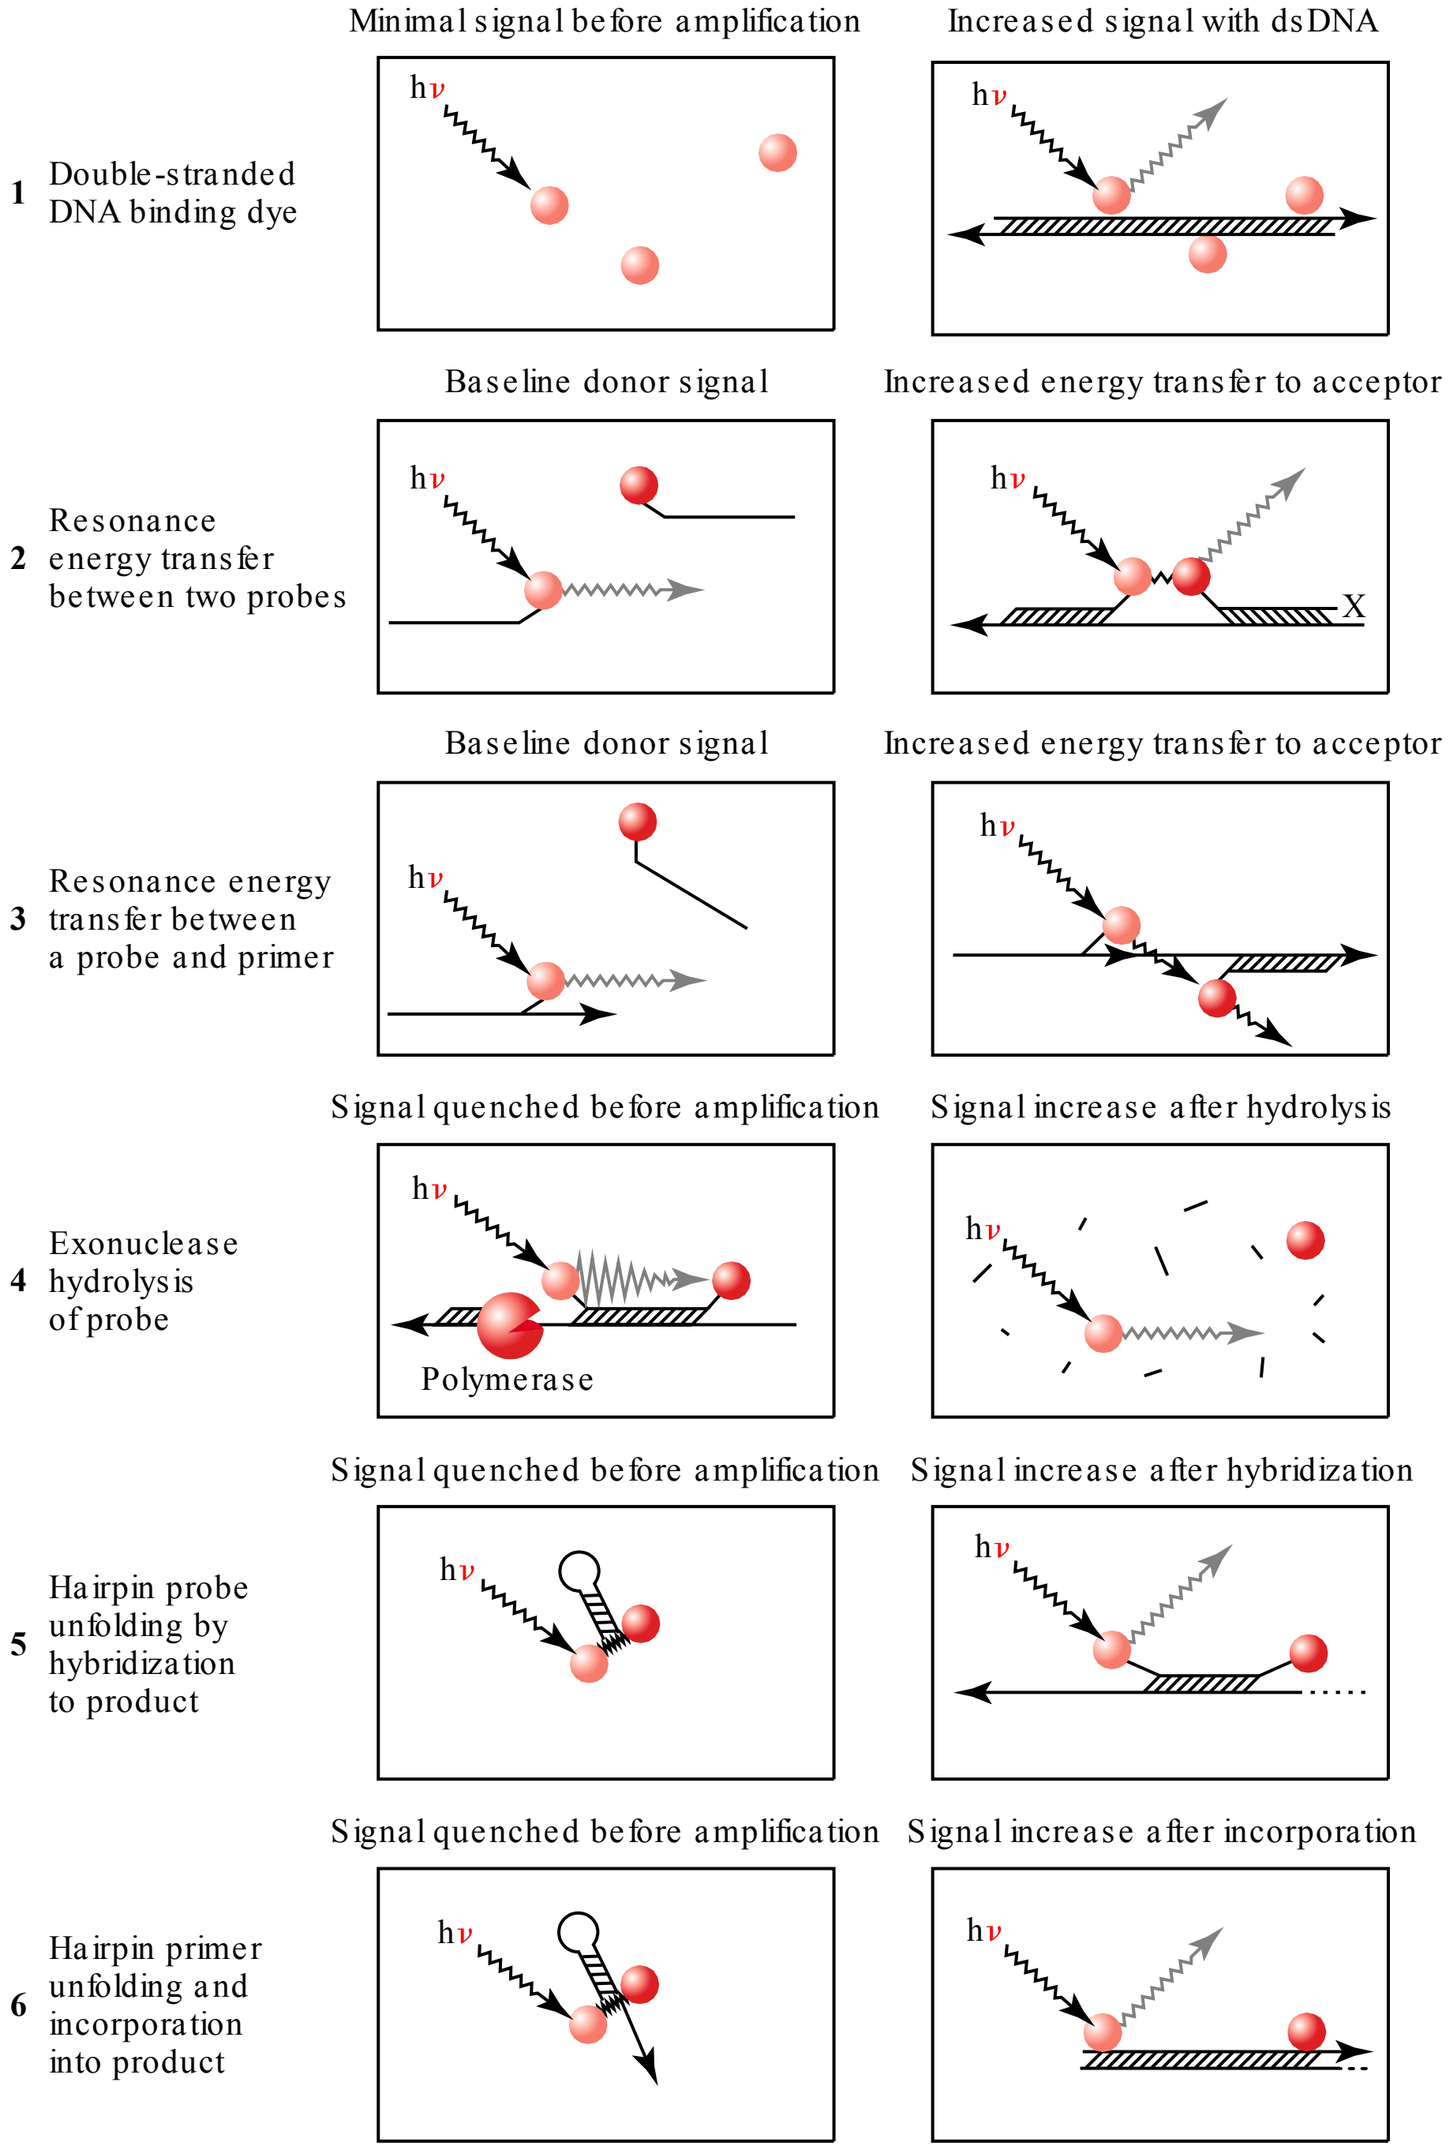

Figure 48-23 Common probes and dyes for real-time polymerase chain reaction (PCR). (1) Double-stranded DNA (dsDNA) dyes show a significant increase in fuorescence when bound to DNA (hv = excitation light). (2) Adjacent hybridization probes. Fluorescence resonance energy transfer (FRET) is illustrated between a donor and acceptor fuorophore. The "x" indicates termination of the 3′-end of the probe to prevent polymerase extension. (3) FRET between a labeled primer and a single hybridization probe. (4) Hydrolysis probes are cleaved between a fuorescent reporter and a quencher, resulting in increased fuorescence. (5) Hairpin probes are quenched in the native conformation, but increase in fuorescence when hybridized. (6) Hairpin primers retain their native, quenched conformation until they are incorporated into a double-stranded product. (Modified with permission of the publisher from Pritham GH, Wittwer CT. Continuous fuorescent monitoring of PCR. J Clin Lig Assay 1998;21:404-12. © 1998 Clinical Ligand Assay Society Inc.)

fluorophore may be necessary if the fluorescence is quenched by deoxyguanosine residues. Another single-labeled probe design uses thiazole orange attached to a PNA. In each of these designs, the fluorescence change with hybridization is reversible with melting.

Hydrolysis Probes. Fluorescent probes have been synthesized with a quencher molecule positioned to quench the fluorescence of another label. If the probe is hydrolyzed between the fluorophore and the quenching molecule during the PCR, fluorescence will increase. T e most common implementation uses the 5′-exonuclease activity of the DNA polymerase to hydrolyze the probe and dissociate the labels (see Figure 48-23, row four). T is method has been simplified by putting the labels on opposite ends of the probe. Hybrid-stabilizing agents, such as a minor-groove (a shallow "furrow" in the molecular structure of a DNA double helix) binder, have been added to the probe to make the system more robust. Dual-labeled probes also have been cleaved using a DNAzyme (a DNA molecule that acts as a catalyst) generated during PCR. Hydrolysis probes generate fluorescence by breaking covalent bonds. T e change in fluorescence is irreversible, and melting analysis of the hydrolyzed probe is not possible.

Mixed Mechanism Probes. Several probe systems appear to function by both hydrolysis and hybridization mechanisms. T ese include (1) hairpin probes, (2) self-probing amplicon primers, and (3) displacement probes. A hairpin

probe functions similarly to a hairpin primer in that it is designed to increase the fluorescence signal when the distance between the quencher and the reporter increases upon target hybridization (see Figure 48-23, row five). Similarly, primers that result in self-probing amplicons have a hairpin that separates quencher from reporter when hybridized. Competitive displacement probes separate quencher and reporter by competitive hybridization. However, in all three cases, polymerases with exonuclease activity are usually used, and the labeled probes are potential substrates for exonuclease cleavage. Indeed, the fluorescence versus cycle number plots often resemble irreversible hydrolysis rather than reversible hybridization (Figure 48-24). Conversely, many hydrolysis probes, especially probes labeled on each end, show significant hybridization signals.

Detection and Quantification in Real-Time Polymerase Chain Reaction

When fluorescence is monitored once each cycle in the presence of SYBR Green I, the data closely follow the expected S-shaped logistic curve (see Figures 48-2 and 48-24, top left). However, with hydrolysis probes, fluorescence is cumulative and continues to increase even after the amount of product reaches a plateau (see Figure 48-24, top middle). In contrast, reactions monitored with hybridization probes may show a decrease in fluorescence at high cycle number (see Figure 48-24, top right). Despite differences in curve shape, all real-time systems follow the amount of product being produced during PCR, and this information is used for detection and quantification.

Detection

A fluorescent signal that increases during PCR and follows one of the expected curve shapes suggests that the specific target is present and was amplified. In contrast, if the background signal remains constant even after 40 to 50 PCR cycles suggests that the target is absent and that no amplification has occurred. Algorithms that analyze the entire curve are more robust than simple threshold methods. Positive controls (to rule out inhibitory factors) and negative controls (to rule out product contamination and nonspecific signal generation) are necessary. If the fluorescent signal is reversible with hybridization, melting analysis is useful to verify the expected Tm of the probe or product.

A note of caution: When specificity of the assay depends only on the primers ("primer-specific detection," as is the case when DNA dyes or labeled primers are used), the possibility of unexpectedly amplifying other targets or primer-dimers is a concern. One technique to eliminate or decrease the detection of unexpected targets is to acquire fluorescence during each cycle at a temperature just below the melting transition of the expected target. To illustrate the concept, Figure 48-25 shows a first-derivative melting curve of products at the end of a PCR that generated unexpected products along with the desired product. The signal was generated with SYBR Green I, a dye that detects all dsDNA. The plot reveals both lower Tm species that are unexpected products and a single Gaussian-shaped peak that is centered on the target's predicted Tm. If fluorescence is acquired during each cycle at (in this case) 85 °C, the unexpected products will be denatured and will not contribute to the signal.

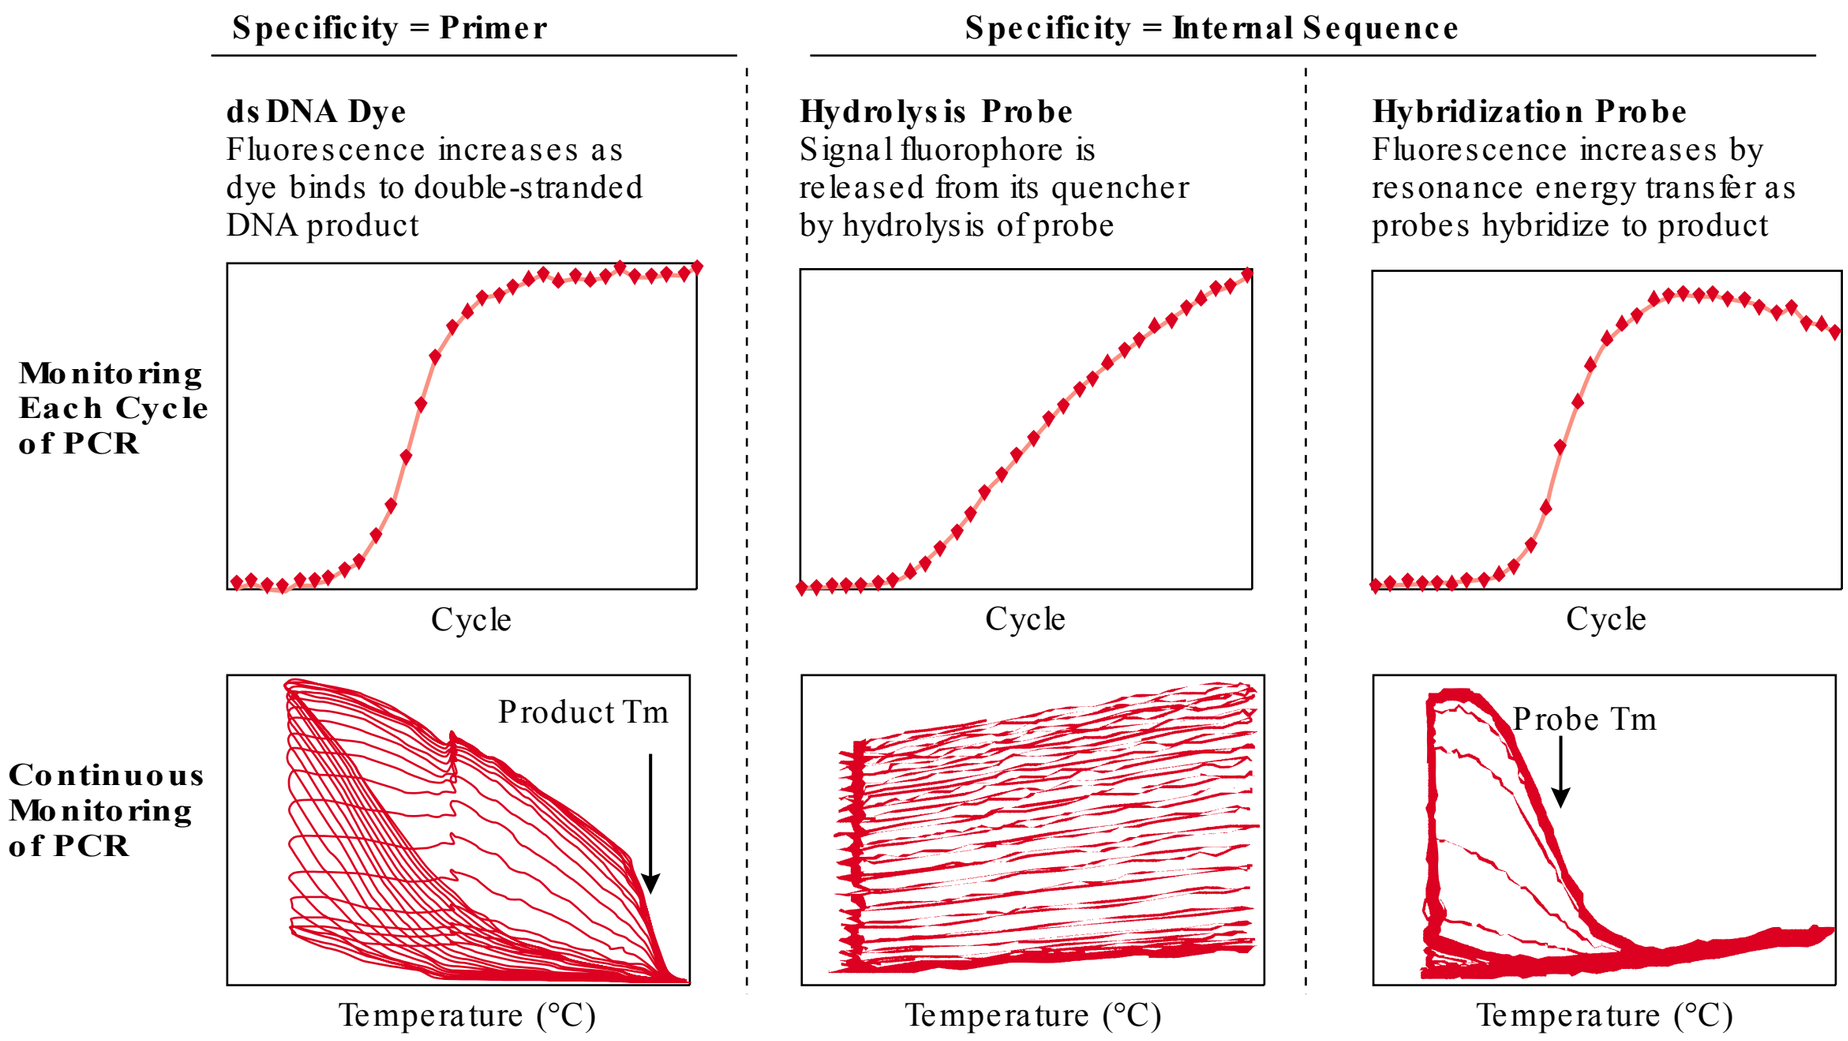

Figure 48-24 Monitoring in real time. The top row shows data collected once each polymerase chain reaction (PCR) cycle, and the bottom row shows data collected continuously (five times per second) during all PCR cycles. Three different reporter systems are shown. (Modified with permission of the publisher from Wittwer CT, Kusukawa N. Real-time PCR. In: Persing DH, Tenover FC, Versalovic J, et al, eds. Molecular microbiology: diagnostic principles and practice. Washington, DC: ASM Press, 2004:71-84.)

Multiplexing of detection is possible with probes that are labeled with different-color dyes or with probes that have different Tm's. Examples in the clinical laboratory include probe multiplexing to detect the presence of more than one infectious organism or to discriminate an internal control template from the target.

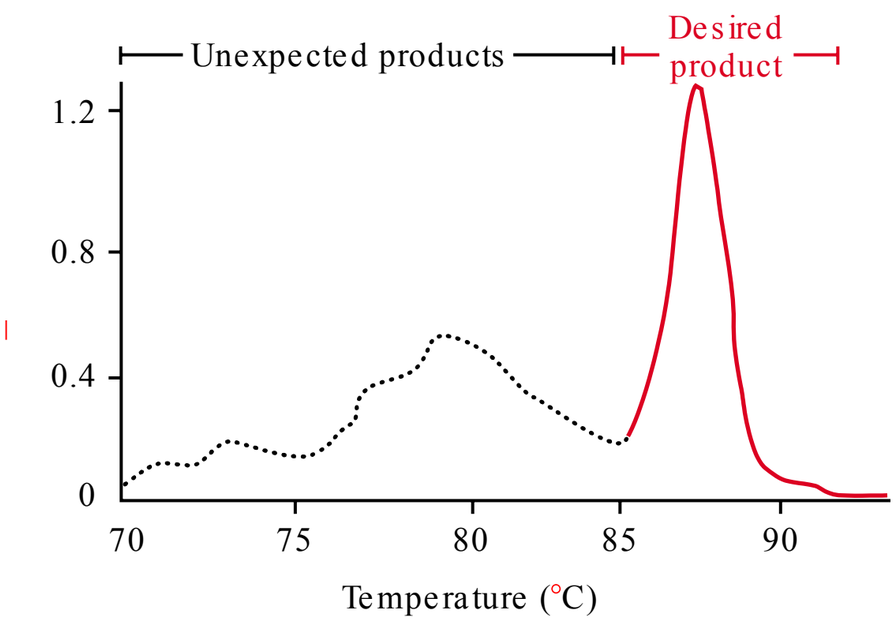

Figure 48-25 First-derivative melting curve showing the target (at high Tm, solid line) and nonspecific polymerase chain reaction (PCR) products (at lower Tm's, dotted line). Biotechniques 1998;24:954-63. © 1998 Eaton Publishing.)

Quantification

Real-time PCR offers a convenient and systematic approach to quantify by monitoring the amount of product produced each cycle. For example, real-time PCR is widely used for the assessment of viral load, particularly for HIV, and other amplification systems, particularly transcription-based and bDNA methods, are also used. Additional quantitative applications of real-time PCR include quantification of mRNAs (after reverse transcription) in gene-expression studies and assessment of gene dosage in genetics and oncology.

One of the advantages of real-time PCR is its large dynamic range. Figure 48-26, Panel A, shows an extended range of external calibrators in a typical real-time PCR. As the initial template concentration increases, the curves shift to earlier cycles. The extent of the shift depends on the PCR efficiency (Table 48-4). The cycle at which fluorescence rises above background correlates inversely with the log of the initial template concentration (Figure 48-26, Panel B). The "cycle" is actually a virtual cycle that includes a fractional component determined by interpolation, which is calculated by several methods. One method uses the maximum second derivative of the curve to determine the cycle number (Figure 48-27). The second derivative is derived from the shape of the curves, and adjustment of baselines and normalization of fluorescence values are not required. Alternatively, in threshold analysis, a fluorescence level is selected that intersects with the amplification curves, and the fractional cycle numbers are found by interpolation.

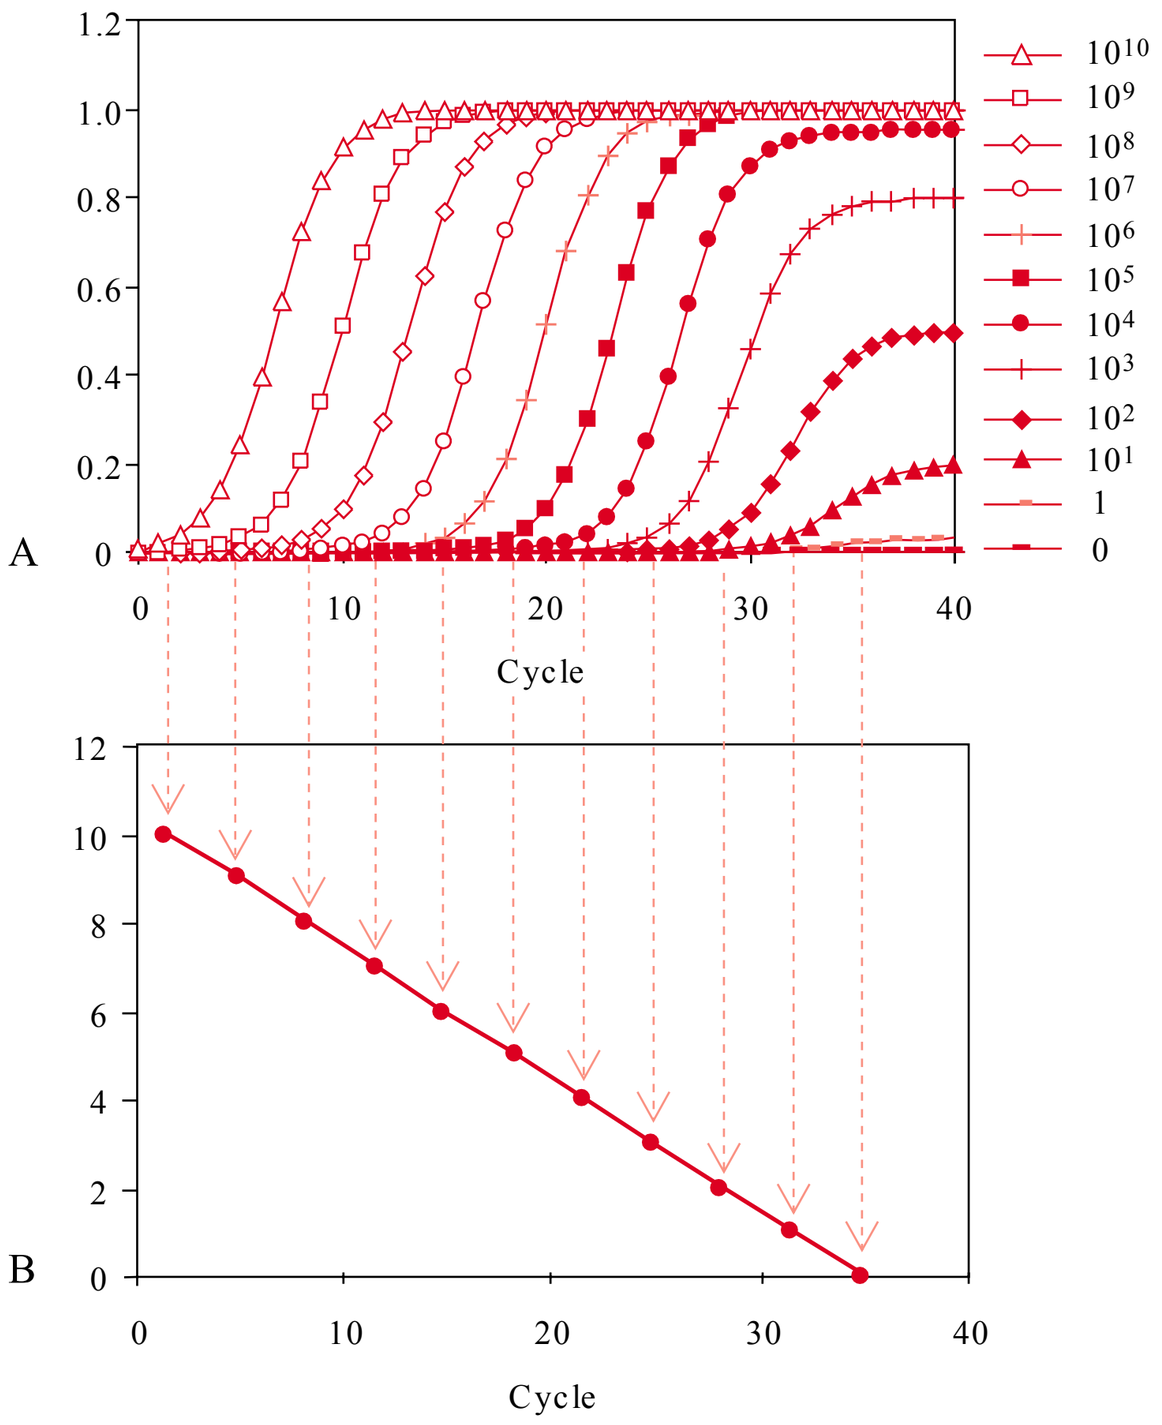

Figure 48-26 Quantification by real-time polymerase chain reaction (PCR). Shown are typical real-time curves for amplification reactions of varying initial target concentrations (A), and the log of the initial concentration plotted against the quantification cycle (B) as calculated by the second derivative maximum. (Modified with permission of the publisher from Wittwer CT, Kusukawa N. Real-time PCR. In: Persing DH, Tenover FC, Versalovic J, et al, eds. Molecular microbiology: diagnostic principles and practice. Washington, DC: ASM Press, 2004:71-84.)

TABLE 48-4 Correlation between Polymerase Chain Reaction Efficiency and Amplification Curve Spacing

PCR Efficiency	Cycles/Log [DNA]*
2.0	3.32
1.9	3.59
1.8	3.92
1.7	4.34
1.6	4.90
1.5	5.68

*The number of cycles that separates each decade difference in initial template concentration (Cycles/log [DNA]) is 1/log (E+1), where E is the PCR efficiency.

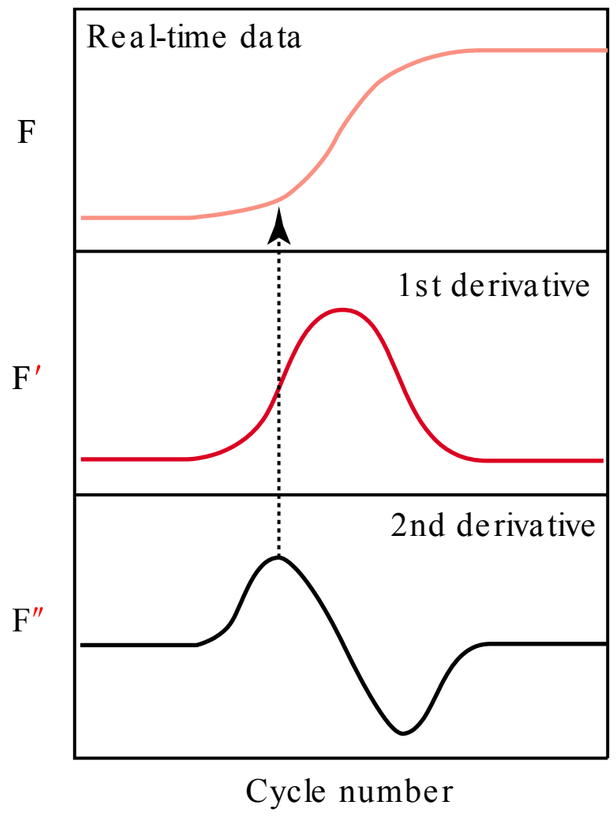

Figure 48-27 Finding the fractional cycle number for quantification. Real-time fluorescence data (F) from the amplification reaction are shown with the first (F′) and second (F″) derivatives. The maximum of the second derivative provides one way to determine the quantification cycle, Cq. (Modified with permission of the publisher from Wittwer CT, Kusukawa N. Real-time PCR. In: Persing DH, Tenover FC, Versalovic J, et al, eds. Molecular microbiology: diagnostic principles and practice. Washington, DC: ASM Press, 2004:71-84.)

Accuracy and Precision

The accuracy of real-time PCR quantification depends not only on the method chosen to analyze the curves but also on the quality of calibrators used. Purified PCR products quantified by spectrophotometry are available and easily obtained. When serially diluted, such products are used as calibrators. Alternatively, purified plasmids or genomic DNA have been used as calibrators. The precision of quantitative real-time PCR depends on the copy number. When the initial target concentration is low, imprecision is high. At least part of the variance comes from stochastic limitations as defined by the Poisson distribution as described earlier.

Melting Curve Analysis

Homogeneous hybridization has been used for (1) amplification, (2) detection, (3) quantification, and (4) obtaining detailed genotyping information. In practice, genotyping is preferably performed in the same tube by monitoring the melting of hybridized duplexes during controlled heating, producing a melting curve signature for the duplex. Such a signature monitors duplex binding over a range of temperatures in contrast to the single-temperature analysis of conventional hybridization techniques, such as dot blots or microarrays. The advantages of complete melting curves also apply when considering only homogeneous techniques. For example, methods that rely on hydrolysis for signal generation and/or those that acquire data only at one temperature generally result in more genotyping errors. Real-time amplification and melting analysis constitute a powerful combination of techniques that only requires temperature control and sampling of fluorescence. Many other genotyping techniques require complex separation and/or detection equipment after PCR. Real-time PCR with melting curve analysis allows (1) amplification, (2) detection, (3) quantification, and (4) genotyping (see Figure 48-22) without ancillary processing or additional equipment. The entire process can be completed in <30 minutes depending on the instrumentation used.

When fluorescence is monitored continuously within each cycle of PCR, the hybridization characteristics of PCR products and probes can be observed (see Figure 48-24, bottom panels). Using SYBR Green I dye, the melting characteristics of the amplified DNA is used to identify the product. No hybridization information is revealed with hydrolysis probes, whereas the melting of hybridization probes is readily apparent. Probe melting occurs at a characteristic temperature that is exploited to confirm target identity and to analyze sequence alterations under the probe. For routine testing in the clinical laboratory, a single melting curve is usually performed at the end of PCR instead of monitoring hybridization throughout the entire PCR process (see Figure 48-22). Immediately after the last PCR cycle, samples are momentarily denatured (94 °C), cooled to about 10 °C below the lowest temperature of interest, and heated at a rate of 0.1 to 0.3 °C/s, while fluorescence is continuously monitored. When hybridization probes are used, rapid cooling maximizes formation of probe-target duplexes while minimizing formation of the duplex PCR product. Primer asymmetry and use of 5′-exonuclease–deficient polymerases may augment the probe signal.

Genotyping of Single-Nucleotide Variants by Melting Curve Analysis

A hybridization probe-pair placed over a heterozygous polymorphism is shown in Figure 48-28. The reporter probe is complementary to the normal allele. As the temperature is increased, the mismatched mutant hybrid dissociates first, giving the first transition, followed by the matched normal hybrid. The Tm's of both hybrids are easily seen in derivative plots. A well-optimized probe design will provide a Tm difference of 4 °C to 10 °C for a single base mismatch under the probe.

SNV genotyping by melting curve analysis has been achieved with a variety of probe and dye methods.[14] Figure 48-29, A, shows the design of traditional hybridization probe pairs and the results

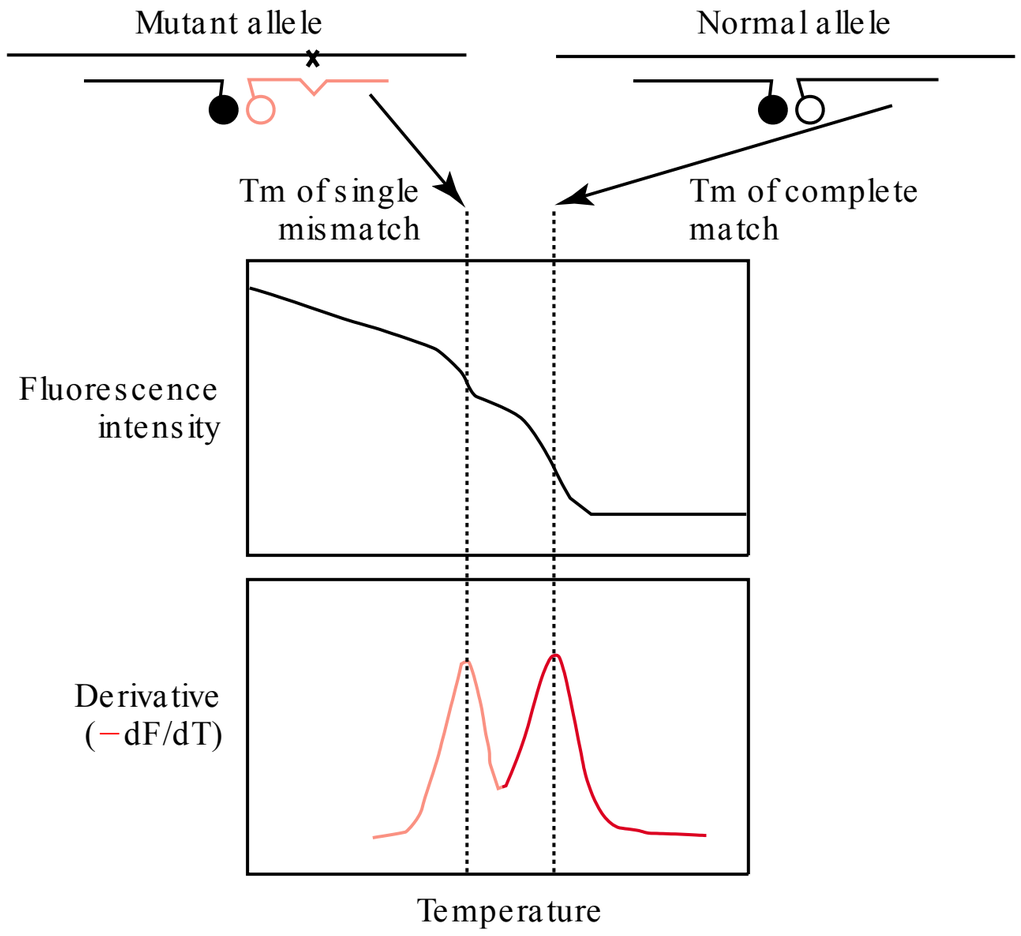

Figure 48-28 Melting curve single-nucleotide variant (SNV) genotyping. A heterozygous specimen with an SNV under the probe is amplified and melted. Two temperature transitions are visible: one from the mutant allele that is mismatched with the probe and melts at a lower temperature, and one from the normal allele that is completely matched with the probe and melts at a higher temperature. The derivative plot shows the melting temperatures of both the mutant-probe and the normal-probe duplexes as peaks. (Modified with permission of the publisher from Bernard PS, Pritham GH, Wittwer CT. Color multiplexing hybridization probes using the apolipoprotein E locus as a model system for genotyping. Anal Biochem 1999;273:221-228. © 1999 Academic Press.)

of (1) homozygous wild-type, (2) mutant, and (3) heterozygous samples that are well discriminated from each other. Virtually the same result is achieved with a single hybridization probe in which the fluorescent signal is quenched on the free probe but increased when it forms a hybrid with the target (Figure 48-29, B). Figure 48-29, C, illustrates genotyping with an unlabeled probe and a saturating DNA binding dye. Both probe and amplicon melting transitions are present. Figure 48-29, D, shows similar results using a snapback primer, an unlabeled probe attached as a 5′-tail to one of the primers. The advantage of these last two methods is that they do not require fluorescently labeled probes. Finally, SNV genotyping is possible by amplicon melting alone if a saturating DNA binding dye is used (Figure 48-29, E). However, the temperature difference between genotypes may be small, and high-resolution melting may be required for accurate genotyping.

High Resolution Melting Curve Analysis

Melting curve analysis with saturating dyes detects single base changes with high sensitivity and does not require processing or separation. Although conventional fluorescent melting analysis can distinguish PCR products with Tm's that differ by 1 °C to 2 °C, high-resolution melting instruments now provide a precision and resolution improvement of at least ten-fold and require only a few minutes. Typically, melting data are normalized between 0% and 100% fluorescence with the background

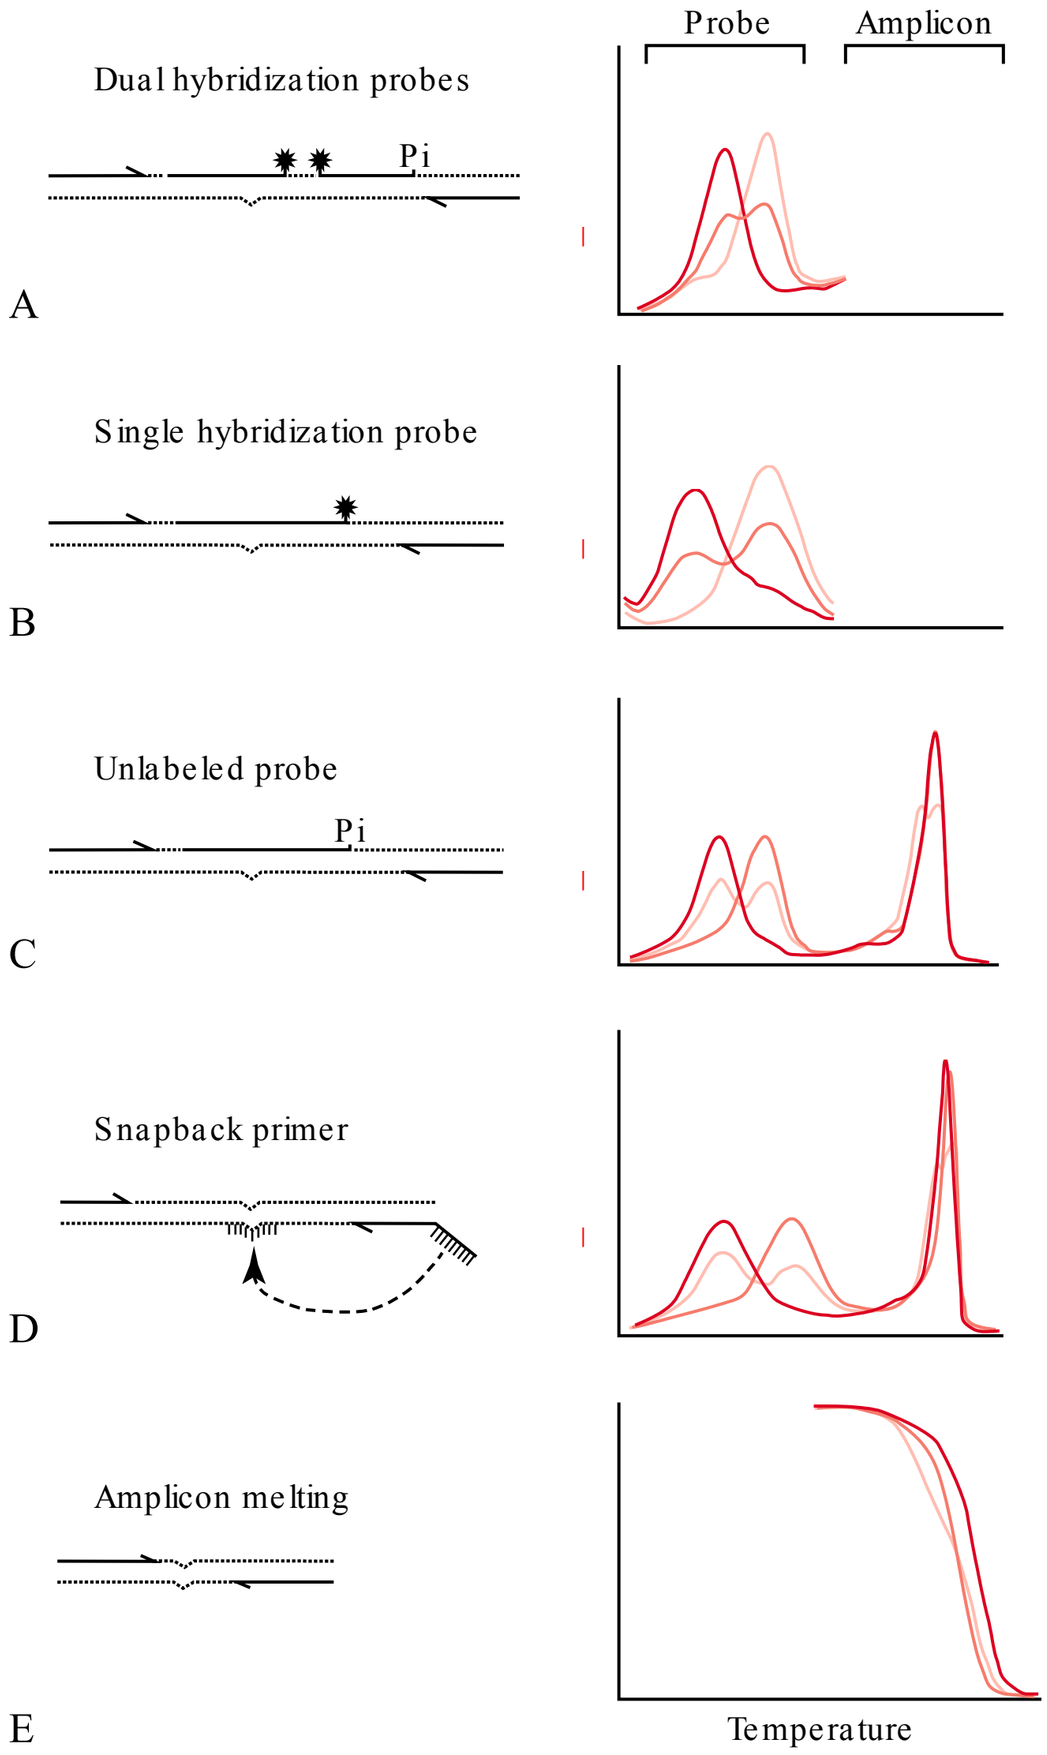

Figure 48-29 Five designs for single-nucleotide variant (SNV) genotyping and corresponding melting curve results. The traditional dual hybridization probe design (A) uses a pair of probes: one labeled with an acceptor fuorophore and the other with a donor fuorophore. The single hybridization probe design (B) lacks the second probe. The unlabeled probe design (C) does not require a covalently attached fuorescent label, using instead a saturating DNA binding dye in solution. Snapback primers (D) are similar to unlabeled probes with the probe attached to one primer as a 5′-tail. Finally, amplicon melting (E) uses only two regular polymerase chain reaction (PCR) primers, relying on high-resolution melting analysis to distinguish the small differences between genotypes. The two homozygotes are differentiated by melting temperature (Tm), and the heterozygote differs in shape from the contribution of heteroduplexes. Pi indicates a 3′-phosphate or other blocker that prevents polymerase extension.

removed to better match predicted helicity. Different homozygotes are distinguished by Tm and heterozygotes are identified by a change in shape. For example, SNV genotyping within a two-domain melting curve is shown in Figure 48-30. Major applications of high-resolution melting include (1) genotyping, (2) mutation scanning, and (3) sequence matching.

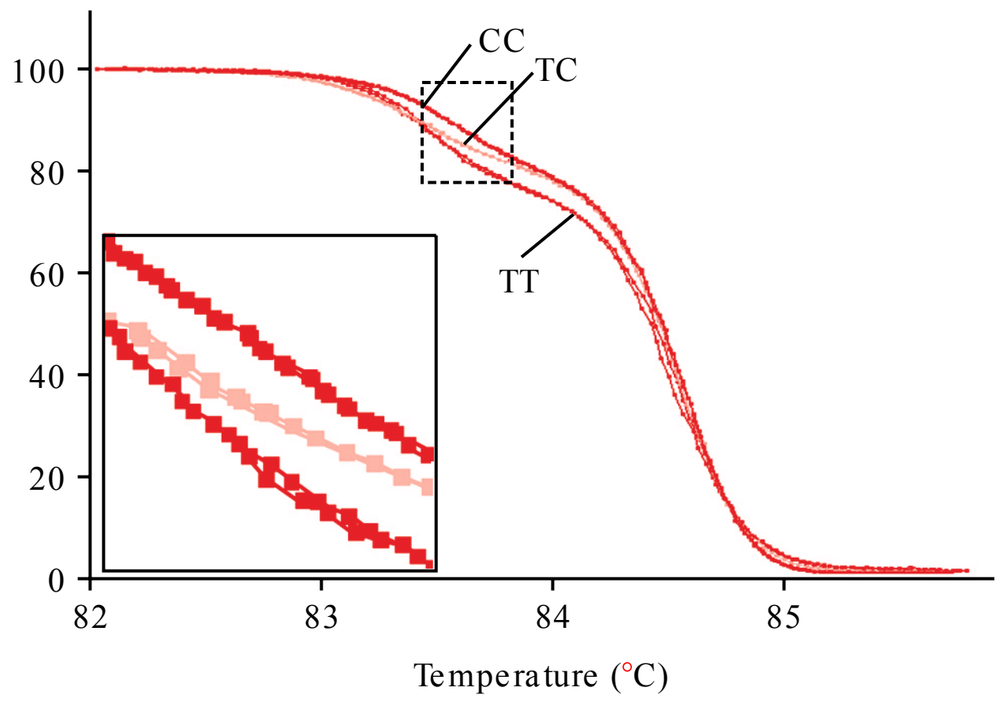

Figure 48-30 A single base change in a 544 bp fragment detected by melting analysis. Shown are high-resolution melting curves of polymerase chain reaction (PCR) amplicons from the gene HTR2A carrying a single-nucleotide variant (SNV). Results are shown for six individuals, two different individuals for each of the three genotypes: wild-type homozygote (TT), mutant homozygote (CC), and heterozygote (TC). Two melting domains are present because of differing GC content. The SNV was present in the lower melting domain. The inset magnifies a portion of the data, showing that all three genotypes can be discriminated. (Modified by permission of the publisher from Wittwer CT, Reed GH, Gundry CN, et al. High-resolution genotyping by amplicon melting analysis using LC Green. Clin Chem 2003;49:853-60. © AACC.)

TABLE 48-5 Comparison of Homogeneous Single-Nucleotide Variant Genotyping Methods (In Order of Increasing Complexity)

Method	Oligonucleotides	Modifications	Comments
Amplicon melting	2	0	Simplest and least expensive
Snapback primers	2	1	Self-complementary 5′ tail
Allele-specific PCR (real time)	3	0	One well for each allele
Unlabeled probes	3	1	3′-block on probe
Allele-specific PCR (melting)	3	1-2	GC clamps as 5′ tails
Single hybridization probe	3	1-2	3′ block if the fuorescent label is 5′
Dual hybridization probes	4	3	Two fuorescent labels and one 3′ block
Hydrolysis probes	4	4	Two fuorescent labels and two quenchers
Hairpin probes	4	4	Two fuorescent labels and two quenchers
Self-probing amplicon	3-4	6	
Minor groove binder hydrolysis	4	6	
Serial invasive signal amplification	5	4	

Comparison of Homogeneous Single-Nucleotide Variant Genotyping Methods

Methods for closed-tube homogeneous SNV genotyping differ greatly in their level of complexity (Table 48-5). For example, the five simplest methods do not use fluorescently labeled probes. Amplicon melting requires only two primers and a heteroduplex-detecting DNA dye (see Figure 48-29, E). The snapback primer system also requires only two primers—one with a self-probing 5′-tail (see Figure 48-29, D). Unlabeled probe genotyping requires two primers and one 3′-blocked probe (see Figure 48-29, C). Allele-specific PCR requires three primers and is based on a preference by the polymerase to extend only a perfectly matched primer. In practice, genotyping is either performed in two wells by monitoring fluorescence at each cycle or in one well by incorporating GC-clamp(s) so that alleles will be differentiated at the end of PCR by their melting temperatures. Intermediate in complexity are hybridization probe melting assays. Designs with single or dual hybridization probes are shown in Figure 48-29, A and B.

The more complex closed-tube methods for SNV genotyping are equilibrium type assays. Allele-specific hydrolysis and hairpin probes are commonly used. Self-probing amplicons and minor groove binder hydrolysis probes both require three modifications on two probes for SNV typing. Finally, serial invasive signal amplification is a method of homogeneous genotyping that does not require PCR.

Review Questions

1. The correct sequence of events during thermal cycling in a polymerase chain reaction (PCR) is
   a. anneal, extend, denature.
   b. denature, anneal, extend.

c. extend, anneal, denature.
d. extend, denature, anneal.

2. Regarding DNA electrophoresis, the type of gel that is used to separate nucleic acid fragments with low resolution between 20 bp up to 10,000 kilobases in length is
   a. agarose gel.
   b. polyacrylamide gel.
   c. polyimide gel.
   d. sucrose gradient gel.
3. In the determination of nucleic acid purity following isolation, the most acceptable A260/280 ratio for DNA is:
   a. 1.2
   b. 1.4
   c. 1.8
   d. 2.1
4. Which component is not part of PCR amplification?
   a. Taq polyermase
   b. Magnesium
   c. dNTPs
   d. Restriction enzyme
5. Another name for a restriction enzyme is
   a. an exonuclease.
   b. an endonuclease.
   c. a polymerase.
   d. a telomerase.
6. An amplification control in an infectious disease molecular assay
   a. is used to quantify unknowns.
   b. can signal a false negative result.
   c. indicates whether there is contamination.
   d. serves as a molecular weight standard.
7. The process of transferring the electrophoresed DNA out of a gel and onto a nylon paper is referred to as
   a. Southern blotting.
   b. Northern blotting.
   c. Western blotting.
   d. hybridization.
8. One of the major advantages of real-time polymerase chain reaction (PCR) compared to conventional PCR is that
   a. there is no need for specialized instruments.
   b. primers are not required.
   c. it can be used to quantify nucleic acid.
   d. it does not require the use of fluorescent compounds.
9. In the polymerase chain reaction (PCR), which one of the following components initiates extension of the sequence of interest by allowing polymerase to "see" single strands of DNA and begin adding nucleotides?
   a. Probe
   b. Ligase
   c. Promoter
   d. Primer
10. Differences observed in the sizes and number of fragments generated by restriction enzyme digestion of DNA is called
    a. restriction fragment length polymorphism (RFLP).
    b. variable number of tandem repeats.
    c. hybridization.
    d. strand displacement.

CHAPTER

49

Genomes and Nucleic Acid Variations

Carl T. Wittwer, M.D., Ph.D., and Noriko Kusukawa, Ph.D.

Objectives

1. Describe the human genome including size and composition; state the size contribution and function (if known) of each of the following genomic elements:
   - Genes
   - Intergenic DNA
   - Mitochondrial DNA
   - Segmental duplications
   - Structural DNA
   - Transposons
2. Compare microsatellite sequences (short tandem repeats [STRs]) to minisatellite sequences (variable-number tandem repeats [VNTRs]), including size, genomic location, role in human disease, and use in nucleic acid testing.
3. Compare single-nucleotide variants (SNVs) to copy number variants (CNVs), including composition, genomic frequency, and role in human disease.
4. For the following, state the specific DNA alteration and how it relates to human disease or gene expression:
   - Copy number variants (CNVs)
   - Deletion
   - Epigenetic alterations
   - Indel
   - Insertion
   - Missense
   - Nonsense
5. Compare the human genome to bacterial, viral, and fungal genomes, including size, complexity, and percent of expressed genes.

Key Words and Definitions

Copy number variant (CNV) A structural variant of a large region of the genome that has been deleted or duplicated.

Deletion A DNA sequence that is missing in one sample compared with another. Deletions may be as small as one nucleotide or as large as an entire chromosome.

Heteroplasmy A condition in which a continuously variable proportion of DNA alleles is possible in a cell; for example, within a single cell, there is a mixture of mitochondria, some containing mutant mitochondrial DNA and some containing normal mitochondrial DNA.

Indel A sequence variant arising from both an insertion and a deletion.

Insertion An extra DNA sequence that is present in one sample compared with a reference sequence.

Intergenic DNA sequence between genes.

Microsatellites Short segments of DNA (1 to 13 bases long) that are repeated end to end. Also known as short tandem repeats (STRs).

Minisatellites Repeated segments of DNA that are 14 to 500 bases long. Also known as sequences with a variable number of tandem repeats (VNTRs).

Missense A nucleotide substitution that changes a codon to the code for a different amino acid. Although these sequence changes are commonly referred to as missense "mutations," this is strictly a misnomer, because they may be benign and cause no disease.

Mutation A disease-causing sequence variation.

Nonsense A nucleotide substitution that results in a stop codon, prematurely terminating the protein.

Oligonucleotide A short single-stranded polymer of nucleic acid.

Plasmid An extrachromosomal ring of double-stranded, closed DNA found in bacteria.

Pseudogene A genetic element that does not code for a functional gene product, usually because of accumulated sequence variations.

Short tandem repeats (STRs) Short segments of DNA (1 to 13 bases long) that are repeated end to end. Also known as microsatellites.

Simple sequence repeats (SSRs) Any sequence repeated over and over again in tandem, such as microsatellites and minisatellites.

Single-nucleotide polymorphism (SNP) A benign single-nucleotide variant (SNV) (substitution, deletion, or insertion) that occurs in the population at a frequency of at least 1%.

Single-nucleotide variant (SNV) Genetic variation of a single nucleotide (substitution, deletion, or insertion). SNVs may be benign or may cause disease.

Transposon A mobile genetic element that can delete and insert itself variably into the genome.

Variable-number tandem repeats (VNTRs) Repeated segments of DNA that are 14 to 500 bases long. Also known as minisatellites.

Variation A change in DNA sequence. It may be benign or may cause disease.

Molecular diagnostics focuses on medically important sequence **variations** within a background of complex genomic structure. This chapter reviews the organization of human, bacterial, viral, and fungal genomes and the spectrum of variations in nucleic acids that are of medical concern.

Genomes and Nucleic Acid Variations

In what follows, the structures of human, bacterial, viral, and fungal genomes are reviewed. Nucleic acid alterations of medical interest are introduced, emphasizing concepts relevant to molecular diagnostics.

Human Genome

Each human cell contains two copies of a 3.08-billion sequence code of nucleic acid bases spread across 46 chromosomes. Box 49-1 lists statistics for the human genome and the types of variations that are important in clinical diagnostics.

Three quarters of human DNA is **intergenic** or between genes. More than 60% of this intergenic sequence consists of "parasitic" DNA regions of transposable elements 100 to 11,000 bases in length. Between 2 million and 3 million of these **transposons** are present in each copy of the genome. They contribute to genetic recombination and chromosome structure and provide an evolutionary record of sequence variation and selection.

Segmental duplications constitute 5.3% of the human genome. They are over 1 kilobase (a thousand bases, or kb) in length and have a sequence identity of at least 90%; they are not transposable. Segmental duplications are common in the human genome and are prone to **deletion** and/or rearrangement, often with medical consequences.

Intergenic DNA also carries most of the **simple sequence repeats (SSRs)** present in the genome. These repeats are known as **microsatellites** or **short tandem repeats (STRs)** when the repeat unit is 1 to 13 bases and **minisatellites** or **variable-number tandem repeats (VNTRs)** when the repeat unit is 14 to 500 bases. SSRs are critical markers in genetic linkage studies and in forensic or medical identity testing. They are formed by slippage during replication and are highly polymorphic between individuals. The most common SSRs are dinucleotide repeats, such as ACACAC and ATAT. On average approximately one SSR has been found every 2000 bases.

Approximately 2% of DNA is required to maintain the structure of chromosomes and is located at chromosome centers (centromeres) and ends (telomeres). Centromeric DNA consists of many tandem copies of nearly identical 171 base pair (bp) repeats encompassing 0.24 to 5.0 Mb per chromosome. Each chromosome end is capped with several kb of the telomeric 6 base repeat TTAGGG.

Although intergenic DNA does not code for protein and was originally considered "junk," much of this DNA is transcribed to RNA, producing a complex "transcriptome" network of RNA control elements whose function and mechanics are active areas of investigation.[1]

One quarter of the human genome consists of genes. There are about 20,000 to 25,000 genes in the human genome. The average gene covers 27,000 bases, but only about 1300 of these bases code for amino acid sequences. The primary RNA transcript is processed by splicing to retain exons that are interspersed throughout the gene and have higher proportions of guanine and cytosine than noncoding regions have. On average, 95% of a gene is excised as introns, retaining a mean of 10.4 exons, of which 9.1 are translated into proteins. Exons make up only 1.9% of the total genome with 1.1% of the genome coding for proteins. Some important genes are present in many copies, so overall protein expression is not affected if a chance variation occurs in one copy. If extra copies of genes lose their function, they are known as **pseudogenes**. At least as many pseudogenes as functional genes are present in the human genome. It is important to distinguish pseudogenes from functional genes because sequence variations in pseudogenes are seldom of clinical importance.

Even though 99% of the genome does not code for protein, most of it is transcribed into noncoding RNA. At least 93% of the genome is transcribed,[1] producing more than ten times the

BOX 49-1 The Human Genome and Its Sequence Variation[4,5,11,12]

The Human Genome

3.08 billion base pairs in 23 chromosomes (46-244 million base pairs per chromosome)

Genes (25%)	Intergenic Sequences (75%)
23% Intron sequence	45% Parasitic (transposon-derived repeats)
1.9% Exon sequence	5% Segmental duplications
1.2% Coding	3% Simple sequence repeats
0.7% Untranslated	2% Structural (centromers, telomers)
	20% Other

Number of genes: 20,000 to 25,000
Average gene: 27,000 base pairs
- 10.4 exons
- 9.1 transcribed exons
- 1340 bases of coding sequence
- 446 amino acids

Sequence variation: 99.9% identity (1 difference every 1250 bases between randomly selected haploid genomes)
Single-nucleotide variants (SNVs): identified every 100 to 300 bases
- 97% Noncoding (average of 126 within each gene)
- 3% Within exons (average of 5 within the coding regions of each gene)
- Copy number variants (CNVs) constitute 5% to 12% of the genome

Disease-Causing Variants

68% SNVs
- 45% Missense (amino acid substitution)
- 11% Nonsense (termination)
- 10% Splicing
- 1%-2% Regulatory
- 24% Small insertions and/or deletions
- 8% Structural (large insertions/deletions, rearrangements, copy number)

Epigenetic Alterations
- Variable initiation
- Alternative splicing
- Cytosine methylation (regulation)
- Histone phosphorylation, methylation, acetylation

amount of RNA that is produced from the coding segments of genes.[2] Both strands of DNA may be transcribed, and long noncoding transcripts may overlap coding regions, producing a complex transcriptome of functional RNA molecules that may variably regulate (1) transcription of coding regions, (2) RNA processing, (3) messenger RNA (mRNA) stability, (4) translation, (5) protein stability, and (6) secretion. In addition to long noncoding RNA, ribosomal RNA, and transfer RNA, specific classes of noncoding RNAs include (1) small nuclear RNAs critical for splicing, (2) small nucleolar RNAs that modify rRNA, (3) telomerase RNAs for maintenance of telomeres, (4) small interfering RNAs, and (5) microRNAs (miRNAs) that regulate gene expression.[8,9] The miRNAs[3] are discussed in more detail in Chapter 47.

Sequence Variation within the Human Genome

Consider the genome as a book. Nucleotides (bases) are the individual letters, and three-base words code for each amino acid. The words are organized into sentences or exons that are separated by periods or introns. Each sentence is further organized into paragraphs or genes. Many paragraphs constitute a chapter or chromosome, and several chapters make up a book or genome. If the DNA of any two individuals is compared, on average one spelling difference is noted every 1250 bases (i.e., approximately 99.9% of the sequence is identical between randomly chosen copies of the genome). However, different individuals (copies of the same book) vary in a subtler way. Some of the pages are copied more than once and may be scattered throughout the book. Such **copy number variants (CNVs)** involve a greater amount of text than the spelling differences with 0.5% of the genome differing on average between two individuals when 50 kb pages are considered,[7] (that is, between individuals, at least five times as many bases are affected by copy number changes as by small sequence differences).

Any sequence change (compared to a reference sequence) is called a sequence variant or variation. Many variations do not affect human health and are benign or silent. For example, most (1) copy-number variations, (2) **single-nucleotide variants (SNVs)**, and (3) SSRs found between genes are seldom associated with disease. Similarly, most of the SNVs within introns, except for splicing and regulatory variants, are not known to affect gene function. In addition, some of the SNVs within exons are silent alterations that do not code for a change in amino acid sequence because of the redundancy in the genetic code. Still other SNVs in exons code for amino acid changes that do not affect protein function. Even such silent SNVs nonetheless may be of interest as genetic markers.

The most common sequence variations are single base changes, also known as SNVs. Millions of SNVs have been described, and many new SNVs continue to be reported. Some SNVs are common in the population, with allele frequencies of 0.1 to 0.5 (i.e., present in 10 to 50 of every 100 copies studied), though other single base changes are very rare. Although an SNV has been identified every 100 to 300 bases, many of these are not found frequently in the population. The vast majority of SNVs (97%) occur in noncoding regions; only 3% of SNVs are associated with exons.

Although SNVs are the most common sequence variant, copy number variants (CNVs) cover more of the genome than SNVs. These CNVs occur in stretches of DNA that may range from 100 bases up to several Mb (megabases, or million bases) in size. CNVs may be duplicated in tandem or may involve complex gains or losses of homologous sequences at multiple sites in the genome. CNV regions exist in every chromosome and involve 5% to 12% of the human genome.[7,10] Most CNVs are inherited and biallelic, similar to **single-nucleotide polymorphism (SNPs)**. More than 6000 CNV loci have been reported, and many of them overlap with genes. Individuals differ on average at more than 200 CNV loci, and these overlap the transcribed regions of more than 100 genes.

Variations That Cause Human Disease

Sequence alterations that are known to cause disease are often called **mutations** or, "disease-causing variants." About 68% of known disease-causing variants involve only a single base. Most of the remaining disease-causing variants (24%) are small insertions or deletions. The remainder (8%) are more complex structural variations.

Single-Nucleotide Variants

Most SNVs that cause disease are **missense** and result in an amino acid substitution, whereas significantly fewer are **nonsense** variants that result in a termination codon and premature polypeptide chain termination. Approximately 10% of disease-causing variants are SNVs that affect splicing sites and result in altered concatenation of coding sequences. Finally, less than 2% of known disease-causing variants are SNVs that affect the regulatory efficiency of transcription by altering promoter and/or enhancer regions in introns or the stability of the RNA transcript.

Small Insertions and Deletions

Small insertion and/or deletion variants account for 24% of variants that cause disease. An **insertion** refers to the presence of extra bases, whereas deletion implies the absence of certain bases in comparison with a reference sequence. Insertions and deletions often cause a shift of the codon reading frame, resulting in altered amino acid sequence downstream of the variation—commonly followed by chain termination from a nonsense codon. An **indel** implies both an insertion and a deletion at the same locus (e.g., replacement of TG with AGGTC).

Structural Variants

The remaining 8% of variants that relate to health and disease are mostly structural variants, including (1) duplications or deletions of entire exons or genes, (2) chromosomal translocations, (3) inversions, (4) SSR expansions (e.g., an increased number of trinucleotide repeats), (5) gene rearrangements (e.g., rearrangements of immunoglobulin genes in B cells that are required for production of antibodies), (6) complex polymorphic loci related to health and disease (e.g., human leukocyte antigen [HLA]), and (7) CNVs.

Interest in CNVs in relation to disease has increased recently as the extent of variation has become clear.[13] CNVs

can involve genes or contiguous sets of genes. When the normal dosage of the gene is two, but more than two functional copies of a gene are present, then the gene is "amplified." If a dosage-sensitive gene, such as HER-2-neu (ERBB2), is amplified, this usually leads to overexpression of messenger RNA and protein, resulting in cellular abnormalities and possible progression to diseases such as cancer. When the normal gene dosage is two, and loss of one of the functional copies of the gene occurs, disorders such as mental retardation and developmental delay may result. Structural variants can be determined by cytogenetic techniques, including (1) karyotyping, (2) fluorescent in situ hybridization, (3) comparative genomic hybridization, and (4) virtual karyotyping by SNV microarrays.

Alterations in Mitochondrial DNA and Hemizygous Genes

Most human genetic material is present in two copies with the exception of the unpaired sex chromosome in males and mitochondrial DNA. The presence of only a single copy of genes on the X and Y chromosome in males leads to well-known sex-linked disorders. In contrast, the 16,500-bp mitochondrial genome is present in more than 1000 copies per cell, constituting about 0.3% of human DNA. Allele fractions may vary over a wide range when all mitochondria in a cell are considered. That is, mitochondrial DNA demonstrates **heteroplasmy** meaning that the ratio of the wild-type allele to a variant allele within a cell can vary almost continuously, sometimes resulting in a wide range of symptoms even when only one sequence variant is involved.

Human Epigenetic Alterations[6]

In addition to the sequence variants considered earlier, epigenetic alterations, including alternative splicing and methylation, affect gene expression. Even though the number of genes may be limited to less than 25,000, variable transcription initiation and exon splicing produce about 90,000 messenger RNA transcripts and protein products.

Methylation of cytosine to 5-methylcytosine occurs frequently; about 70% of cytosine-guanine dinucleotides (CpG) in the human genome are methylated. Although not inherited, interest in this "5th base" has increased as correlations with cancer have been reported. CpG islands are about 1000 bases in length and are often found near the 5′ end of genes. These regions consist of clusters of CpG dinucleotides that are usually not methylated in normal cells. However, CpG methylation correlates with condensed chromatin structure and promoter inactivation; an important example occurs in tumor-suppressor genes.

Since DNA is associated with proteins in nucleosomes, gene expression can be altered by histone phosphorylation, acetylation, and methylation. See Chapter 47 for further discussion of nucleosomes, histone modifications, and other epigenetic alterations and their relation to disease.

Bacterial Genomes

Bacterial genomes are considerably less complex than human or other eukaryotic genomes. Common bacteria have only one chromosome, usually a circular DNA double helix of 4 million to 5 million base pairs, about 1000 times less than the amount of DNA in a human cell. About 90% of the DNA in bacteria codes for protein. There are no introns, but there are multiple small intergenic regions of repetitive sequences that are dispersed throughout the genome. The common bacterium, Escherichia coli, includes about 4300 genes.

In addition to the large circular chromosome that carries essential genes, bacteria also carry accessory genes in smaller circles of double-stranded DNA (ds-DNA) known as **plasmids**. Plasmids range in size from 1000 to more than 1 million base pairs. Plasmids are important in molecular diagnosis of bacterial infections, because they often encode pathogenic factors and antibiotic resistance.

The bacterial repertoire of DNA can be altered by: (1) gain or loss of plasmids; (2) single-base changes, small insertions and deletions as in eukaryotic genomes; and (3) larger segmental rearrangements, including inversions, deletions, and duplications. Some genes, such as those for ribosomal RNA, are present in many copies and have been used to identify species of bacteria. In addition, the intergenic repetitive sequences serve as multiple targets for **oligonucleotide** probes, enabling the generation of unique DNA profiles or fingerprints for individual bacterial strains.

Viral Genomes

Viral genomes are considerably less complex than bacterial genomes. Common viruses that infect humans vary in size from about 5000 to 250,000 bases, or 20 to 1000 times less than the amount of nucleic acid in E. coli. Because viruses use the host's cellular machinery, they do not need as many genes as bacteria do. Small viruses may encode only several genes, but the larger viruses can encode hundreds. The viral genome consists of either DNA or RNA, and the nucleic acid may be single stranded or double stranded, linear, or circular with one or multiple fragments and/or copies per viral particle. As in bacteria, there are no introns. In fact, in some viruses the exons overlap with different reading frames coding different products from the same nucleic acid sequence. Noncoding regions are usually present at the terminal ends of linear genomes. Repeat segments are often found as terminal or internal repeats and may be inverted.

Sequence alterations in viruses are common. Areas of high sequence variation may be interspersed between conserved domains. Higher frequencies of variation have been correlated with lower polymerase fidelity and may allow escape from antibody recognition and from antiviral drugs. Common sequence variants in viruses include single base changes, insertions, and deletions. Sequence diversity within a viral species may be so great that consensus sequences for molecular typing are difficult to find.

Fungal Genomes

Fungi are eukaryotes, and their genomes are more complex than the genomes of bacteria or viruses. Common fungi that cause human disease have genome sizes of 7.5 to 30 million bases and 8 to 14 chromosomes, as well as mitochondrial genomes. Some fungi have diploid genomes, and others

have haploid genomes. Many of their genes have introns. For instance, Aspergillus fumigatus (a fungus that causes allergic reactions and systemic disease with a high mortality rate) has a haploid genome of about 30 million bases with more than 9900 predicted genes on eight chromosomes. Its genes are smaller than human genes, with an average length of 1400 bp and 2.8 exons per gene.

Review Questions

1. A mutation is defined as
   a. the location of a particular sequence on a chromosome.
   b. a proofreading error that occurs during translation.
   c. a disease-causing variant.
   d. a repeated sequence found in an intron within a segment of genomic DNA.
2. If the nucleotide "A" were inserted into the following mRNA strand at the point where the asterisk (*) is, how would sequence change?

   mRNA strand : AAC CGA CUC *UCC AGG UAA GAC

   a. There would be no change in the sequence.
   b. AAC CGA CUC AUC CAG GUA AGA…
   c. ACC CGA CUCA UCC AGG UAA GAG
   d. ACC CGA CUC AUC AGG UAA GAG
3. True or false: 99% of the human genome codes for protein.
   a. True
   b. False
4. The absence of certain bases in a DNA sequence in comparison with a reference sequence is referred to as a(n)
   a. aneuploidy.
   b. deletion.
   c. translocation.
   d. isochrome formation.
5. True or false: Bacterial genomes are more complex than human genomes because of the presence of more genes.
   a. True
   b. False
6. An example of an epigenetic alteration that would affect gene expression is
   a. methylation of cystosine in a cytosine-guanine dinucleotide.
   b. an insertion of an extra base in a gene.
   c. a chromosomal translocation
   d. heteroplasmy.
7. Simple sequence repeats, such as short tandem repeats (STRs) or variable number of tandem repeats (VNTRs), that are highly polymorphic between individuals are formed by
   a. transcription errors.
   b. frameshift mutations.
   c. capping by a six base repeat.
   d. slippage during replication.
8. Regions of the human genome that provide an evolutionary record of sequence variation and selection are referred to as
   a. genes.
   b. chromosomes.
   c. transposons.
   d. transcriptomes.
9. Sequence variations between wild-type alleles and variant alleles in mitochondrial DNA within a cell can vary continuously. This is
   a. heteroplasmy.
   b. translocation.
   c. insertion.
   d. methylation.
10. The explanation as to why not all single-nucleotide variants (SNVs) affect human health and are benign is that
    a. SNVs are unrelated to gene expression.
    b. they involve complex losses of homologous sequences that are unimportant in disease.
    c. they are deleted during replication.
    d. the vast majority of SNVs occur in noncoding regions of the genome.

Table 50-1 Reference Intervals and Values
Table 50-2 Therapeutic and Toxic Levels of Drugs
Table 50-3 Critical Values

*The authors gratefully acknowledge the contributions of William L. Roberts, Edward R. Ashwood, Pennell C. Painter, June Y. Cope, and Jane L. Smith, upon which portions of this chapter are based.

TABLE 50-1 Reference Intervals and Values

Results of laboratory tests have little practical utility until clinical studies have ascribed various states of health and disease to intervals of values. Reference intervals are useful because they attempt to describe the typical results found in a defined population of apparently healthy people. Different methods may yield different values, depending on calibration and other technical considerations. Hence, different reference intervals and results may be obtained in different laboratories. Variability among methods is particularly characteristic of methods that use antibodies to detect the material of interest, and when results are reported as relative units of activity. Values from apparently "healthy" and diseased people may overlap significantly. Therefore reference intervals, although useful as a guide for clinicians, should not be used as absolute indicators of health and disease (see Chapter 5). The reference intervals presented in this chapter are for general informational purposes only. Guidelines for defining and determining reference intervals have been discussed in Chapter 5 and published in the 2010 CLSI C28-A3 guideline ("How to Define and Determine Reference Intervals in the Clinical Laboratory; Approved Guideline—Third Edition"). As stated in several chapters in this textbook, each individual laboratory should generate its own set of reference intervals.

Where both exist, reference intervals are listed in both conventional and international units and are for use in adults in the fasting state unless otherwise stated. Values for other age groups, when included, are clearly identified. Most of the values listed were obtained from chapters in this book. Some were extracted, however, from Tietz clinical guide to laboratory tests, 4th edition, by Alan H. B. Wu (Philadelphia, WB Saunders/Elsevier, 2006), and Tietz textbook of clinical chemistry and molecular diagnostics, 5th edition, by Burtis CA, Ashwood ER, and Bruns DE (St Louis, Saunders/Elsevier, 2012). For several of the specific proteins, reference intervals—obtained after calibration of the analytical system with the international protein reference RPPHS/CRM-470—are listed in Chapter 18.

A valuable source for reference intervals for older methods is http://cclnprod.cc.nih.gov/dlm/testguide.nsf/ (accessed June 17, 2013).

For convenience and to preserve space, we have used the standard abbreviations listed below:

Abbreviation	Term
Amf	Amniotic fuid
CSF	Cerebrospinal fuid
EDTA	Ethylenediaminetetraacetic acid
F^-	Fluoride ion
F^-/Ox	Fluoride ion and oxalate
Hep	Heparin
Occup. exp.	Occupational exposure
Ox	Oxalate
P	Plasma
Plt	Platelets
RBC	Red blood cells
S	Serum
Sal	Saliva
U	Urine
WB	Whole blood

			REFERENCE INTERVALS

TABLE 50-2 Therapeutic and Toxic Levels of Drugs

Therapeutic drug monitoring and detection of drug overdose have become increasingly important aspects of the role of the laboratory in patient care. The information given for drugs in this table has been gathered from published sources. These examples are intended to complement Chapter 30 of this book and do not represent all drugs for which drug testing may be useful. In addition, knowledge and drug measurement methodologies are continuously improving; therefore it may be necessary to supplement the information given here with information obtained from other sources as it becomes available for these and other drugs. Reliable drug analysis information depends on a well-coordinated sample collection, assay methodology characteristics, and patient-associated considerations, such as age, disease state, concomitant drug administration, and clinical procedures that the patient may have undergone. In practice, each organization should have its own set of therapeutic and toxic levels for the drugs it measures.

Many tests for therapeutic drugs require careful timing between administration and sample collection if the measured concentration of the measured drug is to be of optimal use clinically. Drugs are listed by their chemical or generic name, followed by an example of a commercial brand name for the drug (where appropriate). Unless otherwise indicated, target concentrations reflect steady-state, predose (trough) sampling. These targets, as well as toxic thresholds provided, are intended to serve as guidelines and should not be used to optimize drug dosing independently of clinical factors. See Chapter 30 for detailed information about therapeutic drug monitoring regarding these and additional drugs.

TABLE 50-2 Therapeutic and Toxic Levels of Drugs—cont'd

Conversion factors provided represent the free-base form of the parent drug only—not metabolites, unless otherwise indicated. Active metabolites are indicated for many drugs as "+," but therapeutic or toxic concentrations are not routinely provided. Note that calculated conversions to SI units are rounded, unless the value is less than 1.0. For convenience and to preserve space, standard abbreviations commonly used in laboratory medicine are used. Less common abbreviations and some nonstandard abbreviations are given in the following paragraph. Whenever plasma or whole blood is indicated, the recommended preservative is presumed to be ethylenediaminetetraacetic acid (EDTA), although heparin may be acceptable. Separator gel blood collection tubes for serum or plasma are not recommended for drug testing because of possible adsorption of drugs and/or drug metabolites to the gel itself, contributing to the risk of falsely low drug concentrations. Some drugs (e.g., busulfan, olanzapine) are labile and require special handling. Consult laboratory validation data and current literature sources for specific handling recommendations and anticipated stability guidelines.

Abbreviation	Term
AUC	Area under the plasma drug concentration versus time curve
EDTA	Ethylenediaminetetraacetic acid
MIC	Minimum inhibitory concentration
P	Plasma
S	Serum
Therap	Therapeutic
U	Urine
WB	Whole blood

TABLE 50-3 Critical Values

Critical values, also known as panic or alert values, are laboratory results that indicate a life-threatening situation for the patient. Because of their critical nature, urgent notification of a critical value to the appropriate healthcare professional is necessary. Table 50-3 has been adapted from extensive national surveys. The median or average critical limit determined by these surveys is shown. In practice, each organization should have its own set of critical limits and physician notification policy.

Test	Units	Lower Limit	Upper Limit	Comments
Blood Gases				
pH		7.2	7.6	Arterial, capillary
PCO_2	mm Hg	20	70	Arterial, capillary
PO_2	mm Hg	40	—	Arterial
PO_2 (children)	mm Hg	45	125	Arterial
PO_2 (newborn)	mm Hg	35	90	Arterial
Chemistry				
Albumin (children)	g/dL	1.7	6.8	Serum or plasma
Ammonia (children)	µmol/L	—	109	Plasma
Bilirubin (newborn)	mg/dL	—	15	Serum or plasma
Calcium	mg/dL	6.0	13	Serum or plasma
Calcium (children)	mg/dL	6.5	12.7	Serum or plasma
Calcium, ionized	mmol/L	0.75	1.6	Plasma
Carbon dioxide, total	mmol/L	10	40	Serum or plasma
Chloride	mmol/L	80	120	Serum or plasma
Creatinine	mg/dL	—	5.0	Serum or plasma
Creatinine (children)	mg/dL	—	3.8	Serum or plasma
Glucose	mg/dL	40	450	Serum or plasma
Glucose (children)	mg/dL	46	445	Serum or plasma
Glucose (newborn)	mg/dL	30	325	Serum or plasma
Glucose, CSF	mg/dL	40	200	CSF
Glucose, CSF (children)	mg/dL	31	—	CSF
Lactate	mmol/L	—	3.4	Plasma
Lactate (children)	mmol/L	—	4.1	Plasma
Magnesium	mg/dL	1.0	4.7	Serum or plasma
Osmolality	mOsm/kg	250	325	Serum or plasma
Phosphorus	mg/dL	1.0	8.9	Serum or plasma
Potassium	mmol/L	2.8	6.2	Serum or plasma
Potassium (newborn)	mmol/L	2.8	7.8	Serum or plasma
Protein (children)	g/dL	3.4	9.5	Serum or plasma
Protein, CSF (children)	mg/dL	—	188	CSF
Sodium	mmol/L	120	160	Serum or plasma
Urea nitrogen	mg/dL	—	80	Serum or plasma
Urea nitrogen (children)	mg/dL	—	55	Serum or plasma
Uric acid	mg/dL	—	13	Serum or plasma
Uric acid (children)	mg/dL	—	12	Serum or plasma
Hematology				
Hematocrit				
Adult	%	20	60	First report only
Newborn	%	33	71	
Hemoglobin				
Adult	g/dL	7	20	First report only
Newborn	g/dL	10	22	
WBC				
Adult	$\times 10^3/\mu L$	2.0	30	First report only
Children	$\times 10^3/\mu L$	2.0	43	
Platelets	$\times 10^3/\mu L$	40	1000	
Blasts	Any seen (first report only)			
Drepanocytes	Presence of sickle cells or aplastic crisis			
Coagulation				
Fibrinogen	mg/dL	100	800	
Prothrombin time	s	—	30	
Partial thromboplastin time	s	—	78

Glossary

Absorbance (A) T e amount of light absorbed as incident light passes through a sample, which is equivalent to log (1/T) or −log (T), where T is transmittance.

Absorptivity (a) A proportionality constant for a compound that is the measure of the absorption of radiant energy at a given wavelength as it passes through a solution of that compound at a concentration of 1 g/L; expressed mathematically as absorbance divided by the product of the concentration of a substance in g/L and the sample path length in centimeters (a = A/bc).

Acid phosphatase All phosphatases with optimal activity below pH 7.0 that catalyze the cleavage of orthophosphate from orthophosphoric monoesters; most of the activity in serum is of a tartrate-resistant type.

Acid-base balance T e homeostatic maintenance of acids and bases within the body to achieve a physiological pH (approximately 7.40).

Acidemia An arterial blood pH <7.35.

Acidosis Accumulation of acid and hydrogen ions or depletion of the alkaline reserve (bicarbonate content) in the blood and body tissues.

Acrodermatitis enteropathica A hereditary disorder due to defective zinc uptake.

Acromegaly A chronic disease of adults caused by hypersecretion of pituitary growth hormone and characterized by enlargement of many organs and parts of the skeleton and soft tissues.

Activator Small molecule or ion that increases the rate of an enzyme-catalyzed reaction by promoting formation of the most active state of the enzyme or of other reactants such as the substrate.

Active center/Active site T at part of an enzyme formed by the tertiary structure at which the noncovalent binding of substrate occurs to form the intermediate enzyme/substrate complex.

Activity (Ion) T e concentration of free, unbound ions in solution.

Acute coronary syndrome (ACS) A sudden cardiac disorder that varies from angina (chest pain on exertion with reversible tissue injury), to unstable angina (with minor myocardial injury), and to myocardial infarction (with extensive tissue necrosis, which is irreversible).

Acute fatty liver of pregnancy A rare, life-threatening complication of pregnancy that occurs in the third trimester or the immediate period after delivery.

Acute kidney injury (AKI) A rapid decline in kidney function that occurs over hours and days.

Acute lymphoblastic leukemia (ALL) An acute, rapidly progressing form of leukemia that is characterized by the presence in the blood and bone marrow of large numbers of unusually immature white blood cells destined to become lymphocytes.

Acute myocardial infarction (AMI) An acute infarction (obstruction of circulation) of the heart muscle occurring during the period when circulation to a region of the heart is obstructed and necrosis is occurring.

Acute nephritic syndrome T e sudden onset of hematuria, proteinuria, diminished urine production, azotemia, hypertension, and edema.

Acute pancreatitis A sudden inflammation of the pancreas that is usually accompanied with severe upper abdominal pain.

Acute phase reaction (APR) A response of the body to inflammation that results in an increase or decrease in the plasma concentrations of a class of proteins known as acute phase reactants.

Acute porphyrias Inherited disorders of heme biosynthesis, characterized by acute attacks of neurovisceral symptoms; potentially life threatening; diagnosed by elevated urine PBG.

Acute intermittent porphyria (AIP) An autosomal dominant hepatic porphyria caused by mutation in the HMBS gene (locus: 11q23.3), which encodes hydroxymethylbilane synthase.

Acute poststreptococcal glomerulonephritis (APSGN) Inflammation of the kidney glomeruli, following a streptococcal infection; also called postinfectious glomerulonephritis.

Acute tubular necrosis Acute renal failure with mild to severe damage or necrosis of tubule cells.

Acute-phase response Body's response to injury or inflammation.

Acylglycerol (glycerol ester) A three-carbon alcohol that contains a hydroxyl group on each of its carbons and is classified by the number of fatty acyl groups present; triglycerides are the predominant form of glycerol ester in plasma.

Addison disease Deficiency of adrenocortical hormones secondary to disease of the adrenal glands; characterized by hypotension, and a bronzelike hyperpigmentation of the skin. Also called primary hypoadrenalism to distinguish from secondary hypoadrenalism (deficiency of pituitary adrenocorticotropic hormone).

Additives Compounds added to biological specimens to prevent them from clotting or to preserve the constituents of a specimen.

Adenocarcinoma A carcinoma derived from glandular tissue.

Adenohypophysis The anterior glandular lobe of the pituitary gland.

Adenoma A benign epithelial tumor in which the cells form recognizable glandular structures or in which the cells are derived from glandular epithelium.

Adenylate cyclase An enzyme of the lyase class that catalyzes the formation of 3′,5′-cyclic adenosine monophosphate (cAMP) from ATP.

Adrenal androgens A class of sex hormones that produce masculinization.

Adrenocorticotropic hormone (ACTH, corticotropin) A 39-amino-acid peptide hormone secreted by the anterior pituitary gland that stimulates the adrenal cortex to secrete corticosteroids.

Adsorption chromatography A separation mechanism based on the differential adsorption of analytes on the surface of a stationary phase and using hydrogen bonding and hydrophobic interactions as the forces behind the separation.

Advanced glycation end products (AGE) Proteins that have been irreversibly modified by nonenzymatic attachment of glucose; may contribute to the chronic complications of diabetes.

Adverse drug reaction (ADR) Any undesirable side effect or toxic reaction that is caused by the administration of a drug.

Adverse Reaction to Metal Debris (ARMD) A condition characterized by severe hip pain that results from metal released when the ball and joint of the prosthesis used in a hip replacement are both metal.

Adynamic bone disease (ABD) A type of renal osteodystrophy characterized by reduced osteoblasts and osteoclasts, and low turnover of bone.

Affinity Energy of interaction of a single antibody-combining site and its corresponding epitope on the antigen.

Affinity chromatography A separation mechanism in which one component of a specifically matched pair (such as antigen/antibody or hormone/receptor) is immobilized in a stationary phase and is used to capture the other component of the pair that is in the mobile phase.

Alcoholic hepatitis An acute or chronic degenerative and inflammatory lesion of the liver in the alcoholic that is potentially progressive though sometimes reversible.

Alcoholic liver disease Liver injury caused by excessive ethanol (alcohol) ingestion.

Aldehyde An organic compound with a carbonyl group (a carbon atom double-bonded to an oxygen) at the end of the carbon chain bonded to hydrogen and an R group (usually an alkyl group).

Aldolase An enzyme that catalyzes cleavage of fructose-1,6-disphosphate into dihydroxyacetone-phosphate and glyceraldehyde 3-phosphate in the glycolytic breakdown of glucose to lactate.

Aldosterone The major mineralocorticoid steroid hormone secreted by the adrenal cortex.

Alkalemia An arterial blood pH >7.45.

Alkaline phosphatase A hydrolase that catalyzes the alkaline hydrolysis of a large variety of naturally occurring and synthetic substrates.

Alkaptonuria A genetic disorder of phenylalanine and tyrosine metabolism that is caused by a deficiency of the enzyme homogentisic acid (HGA) dioxygenase.

Allan-Herndon-Dudley syndrome An X-linked syndrome caused by mutations in the SLC16A2 gene (locus: Xq13.2), which encodes a thyroid hormone transporter, and characterized by severe mental retardation, dysarthria, athetoid movements, muscle hypoplasia, and spastic paraplegia.

Allele One of the alternative versions of a gene at a given location (locus) along a chromosome. An individual inherits two alleles for each gene, one from each parent. If the two alleles are the same, the individual is homozygous for that gene. If the alleles are different, the individual is heterozygous. The term now also refers to variation among noncoding DNA sequences in addition to genes.

Allele-specific PCR A version of polymerase chain reaction (PCR) in which specific alleles or DNA sequence variants are amplified at the same locus.

Alpha fetoprotein (AFP) A protein produced in the fetal liver that is measured in maternal serum for predicting risk of anencephaly, spina bifida, and Down syndrome in the fetus.

5-Aminolevulinic acid (ALA) Immediate precursor of porphobilinogen; two molecules of ALA combine to form one molecule of porphobilinogen.

Amenorrhea The absence of menstruation.

Amino acid An organic compound containing both amino (−NH2) and carboxyl (−COOH) functional groups.

Aminoacidopathy Any one of a group of inborn errors of amino acid metabolism caused by (1) defective activity of an enzyme in the metabolic pathway of one or more amino acids or (2) a defect in a protein needed for transport of an amino acid into or out of cells. They are usually detected by the presence of increased concentrations of one or more amino acids in blood or urine or both.

Aminoaciduria An excess of amino acids in the urine.

Aminotransferases A subclass of enzymes of the transferase class that catalyze the transfer of an amino group from a donor (generally an amino acid) to an acceptor (generally a 2-oxo acid). Most of these enzymes are pyridoxyl phosphate proteins. Alanine and aspartate aminotransferase are examples that are of significant clinical utility.

Amniotic fluid Substance derived mostly from fetal urine that protects the developing fetus.

Amperometry An electrolytic electrochemical process in which current is monitored at a fixed (controlled) voltage between working and reference electrodes in an electrochemical cell.

Amphetamine A sympathomimetic amine that has a stimulating effect on the central and peripheral nervous systems.

Ampholyte A molecule that is positively or negatively charged on the basis of the pH of the solution in which it resides;

proteins, because they contain many ionizable amino and carboxyl groups, behave as ampholytes in solution and are considered amphoteric.

Amplicon The product of an amplification reaction.

Amplification methods Techniques to amplify the amount of target, signal, or probe so that specific sequences are readily observed.

α-Amylase An enzyme that catalyzes the hydrolysis of 1,4-alpha-glycosidic linkages in starch, glycogen, and related polysaccharides and oligosaccharides.

Amyloidosis A metabolic disease characterized by abnormal deposits of amyloid in the body.

Analgesics Agents that relieve pain without causing loss of consciousness.

Analyte The substance being analyzed in an analytical procedure.

Analytical sensitivity The ability of an analytical method to assess small variations in the concentration of analyte.

Analytical specificity The ability of an assay procedure to determine specifically the concentration of the target analyte in the presence of potentially interfering substances or factors in the sample matrix.

Androgen insensitivity syndrome (AIS) A genetic disorder in which XY male fetuses are unresponsive to androgens and are born looking externally like normal females.

Androstenedione An androgenic steroid produced by the testis, adrenal cortex, and ovary.

Anemic hypoxia Hypoxia (a reduced supply of oxygen to the tissues) resulting from a decrease in amount of hemoglobin or number of erythrocytes in the blood.

Anencephaly A birth defect characterized by a brain, skull, and scalp that does not develop normally.

Angina A condition marked by severe pain in the chest, often also spreading to the shoulders, arms, and neck, caused by an inadequate blood supply to the heart.

Angiotensin II A small (eight-amino-acid) polypeptide hormone; it stimulates release of aldosterone and other hormones, constricts blood vessels, and controls arterial pressure.

Angiotensin-converting enzyme (ACE) Enzyme that catalyzes the removal of two amino acids from angiotensin I, thus converting it to the active hormone angiotensin II.

Angiotensin-converting enzyme inhibitors Pharmaceuticals that are competitive inhibitors of the angiotensin-converting enzyme. They are used in the treatment of hypertension.

Angiotensinogen A serum globulin formed by the liver that is cleaved by renin to produce angiotensin I.

Anion gap (AG) The difference between the serum sodium concentration and the sum of the serum chloride and bicarbonate concentrations; the anion gap is high in some forms of metabolic acidosis.

Antibody Immunoglobulin (Ig) class of molecule (e.g., IgA, IgG, IgM) that binds specifically to an antigen or hapten.

Anticholinergic agent An agent that opposes the effects of impulses conveyed by adrenergic postganglionic fibers.

Anticoagulant Any substance that prevents blood from clotting.

Antidiuretic hormone (ADH; vasopressin) An octapeptide hormone formed by the neuronal cells of the hypothalamic nuclei and stored in the posterior lobe of the pituitary gland (neurohypophysis). It has both antidiuretic and vasopressor actions.

Antigen Any material capable of reacting with an antibody without necessarily being capable of inducing antibody formation.

Antihistamines Antagonists of the H1 or H2 histamine receptors that are used to treat allergic reactions or gastric hyperacidity.

Antiporter A membrane transport protein that mediates the cotransport of substances in opposite directions.

Antisense RNA (asRNA) A single-stranded RNA that is complementary to a messenger RNA (mRNA) strand transcribed within a cell.

Apathetic hyperthyroidism A form of Graves disease that tends to affect mainly older adults who have stereotyped "senile" physical features and whose behavior is apathetic (indifferent) and inactive rather than hyperkinetic.

Apoenzyme The protein component of an enzyme.

Apolipoproteins The major protein components of lipoproteins.

Apoptosis Programmed cell death as signaled by the nuclei in normally functioning human and animal cells when age or state of cell health and condition dictates.

Arginine vasopressin (AVP) A peptide hormone also known as antidiuretic hormone (ADH) and vasopressin (VP) that is synthesized in the hypothalamus, but released from the posterior pituitary lobe.

Argininosuccinate lyase (AL) deficiency A genetic disorder that affects the body's ability to clear the nitrogen already incorporated into the urea cycle as argininosuccinate. This disorder often presents with rapid-onset hyperammonemia in the newborn period. Also known as argininosuccinic aciduria.

Argininosuccinate synthetase (ASS) deficiency A genetic disorder characterized by a deficiency of argininosuccinate and an increase in the ammonia concentration in the blood. Also known as citrullinemia type I.

Argonaute proteins Proteins of the RNA-induced silencing complex (RISC), the complex responsible for the gene silencing process known as RNA interference (RNAi).

Argyria A permanent ash gray discoloration of the skin, conjunctiva, and internal organs that results from long-continued use of silver salts.

Array An ordered linear, two-dimensional, or three-dimensional arrangement of a multiplicity of discrete objects, such as individual deposits (spots or lines) of DNA or reaction chambers.

Arrhythmia Any variation from the normal rhythm of the heartbeat; alternative (and broader) term: dysrhythmia, especially to indicate an abnormally slow or fast heartbeat which may have rhythmic beating.

Ascites Fluid accumulation in the abdominal cavity.

Assisted reproductive technologies (ART) Procedures involving the manipulation of eggs or sperm to establish pregnancy in the treatment of infertility.

Asymmetric PCR A version of PCR that preferentially amplifies one strand of the target DNA.

Atherosclerosis A pathogenic process that is the underlying cause of the common cardiovascular disorders of (1) myocardial infarction, (2) cerebrovascular disease, and (3) peripheral vascular disease.

Atherosclerotic plaque A pearly white area within the wall of an artery that causes the intimal (interior) surface to bulge into the lumen; composed of lipid, cell debris, smooth muscle cells, collagen, and sometimes calcium; also known as an atheroma; vulnerable to rupture that causes the formation of a platelet- and fibrin-rich thrombus leading to myocardial infarction and ischemic stroke.

Atomic absorption (AA) spectrophotometry An emission technique in which an element in a sample is dissociated from its chemical bonds (atomized) and placed in an unexcited or ground state (neutral atom); the atom at low energy is able to absorb radiation and the radiant energy given off as the element returns to its ground state is measured.

ATSDR Agency for Toxic Substances and Disease Registry.

Autocrine A mode of hormone action in which a cell secretes a hormone that binds to autocrine receptors on that same cell, leading to changes in the cell.

Autoimmune hepatitis (AIH) A form of hepatitis, usually with hypergammaglobulinemia and serum autoantibodies.

Autoimmune thyroid disease (AITD) Diseases in which the immune system attacks or stimulates the body's own thyroid gland.

Automation The process whereby an analytical instrument performs many tests with only minimal involvement of an analyst; also defined as the controlled operation of an apparatus, process, or system by mechanical or electronic devices without human intervention.

Autosomal recessive disorder A disorder characterized by the requirement that both copies of a gene are abnormal (see following definition for autosomal recessive inheritance).

Autosomal recessive inheritance A Mendelian inheritance pattern in which (1) nonsex chromosomes (autosomes) carry a DNA sequence (gene) for the inherited trait and (2) two copies of the DNA sequence must be present for the trait to appear in an individual; heterozygous parents have a 25% chance of having an affected offspring.

Autosome A nonsex chromosome; there are 22 pairs of autosomes in the human genome.

Avidity Overall strength of binding of antibody and antigen; includes the sum of the binding affinities of all individual combining sites on the antibody.

Avitaminosis A disease condition, described as a deficiency syndrome, that results from lack of a vitamin.

Azotemia An excess of urea or other nitrogenous compounds in the blood.

Bandpass The range of wavelengths passed by a filter or a monochromator at one-half the peak transmittance of that filter.

Barbiturate Any of a class of sedative-hypnotic agents derived from barbituric acid or thiobarbituric acid and classified into long-, intermediate-, short-, and ultrashort-acting classes.

Bartter syndrome Hypertrophy and hyperplasia of the juxtaglomerular cells, producing hypokalemic alkalosis and hyperaldosteronism.

Base pair A purine/pyrimidine pair linked by hydrogen bonds that connects the complementary strands of DNA or of hybrid molecules joining DNA and RNA. The base pairs are adenine-thymine and guanine-cytosine in DNA, and adenine-uracil and guanine-cytosine in RNA.

Base peak The ion with the highest abundance in the mass spectrum; it is assigned a relative abundance of 100%.

Batch analysis Type of analysis in which many specimens are grouped in the same analytical session.

Beer's law A mathematical equation that states that the con of a substance is directly proportional to the amount of light absorbed or is inversely proportional to the logarithm of the transmitted light; mathematically expressed as A = abc.

Bence-Jones proteins Small light chains of immunoglobulin found in the urine.

Benign prostatic hyperplasia (BPH) A noncancerous enlargement of the prostate gland.

Benzodiazepines Any of a group of minor tranquilizers that have a common molecular structure and similar pharmacological activity, including antianxiety, sedative, hypnotic, amnestic, anticonvulsant, and muscle-relaxing effects.

Beriberi A disease caused by a deficiency of thiamine (vitamin B1) and characterized by polyneuritis, cardiac pathology, and edema.

Berylliosis A hypersensitivity response to beryllium, usually involving the lungs and less often the skin, subcutaneous tissues, lymph nodes, liver, or other structures. Two varieties are distinguished: acute b. and chronic b. Called also beryllium poisoning.

beta-Lipotropin (β-LPH) An 89-amino-acid polypeptide hormone synthesized by the anterior pituitary; it exerts a mild peripheral lipolytic action and serves as a precursor of several hormones.

Bezoar A concretion of foreign material found in the gastrointestinal tract or urinary tract.

Bias In an analytical method, the difference between the average value and the true value that is expressed numerically and is inversely related to the trueness.

Bile A greenish-yellow fluid secreted by the liver and stored in the gallbladder.

Biliary atresia A condition characterized by failure of a fetus to develop an adequate pathway for bile to drain from the liver to the intestine.

Biliprotein The conjugated bilirubin-protein complex (also known as delta-bilirubin).

Bilirubin A yellow bile pigment that is a breakdown product of heme mainly formed from the degradation of erythrocyte hemoglobin in reticuloendothelial cells.

Bioavailability The degree to which a drug or other substance becomes available to the target tissue after administration.

Bioluminescence The emission of light when an electron returns from an excited or higher energy level to a lower energy level in which the excitation event is caused by a biochemical reaction and not by photo illumination; a

special form of chemiluminescence in which an enzyme or a photoprotein increases the ef ciency of the light emission.

Biomarker In medicine, a biomarker is a biological compound that is used as an indicator of a particular disease state or some other physiological state of an organism.

Biosensor A type of chemical sensor consisting of a biological recognition element and a physicochemical transducer, often an electrochemical or an optical device.

Biotransformation T e series of chemical alterations of a compound (for example, a drug) that occurs within the body, as by enzymatic activity.

Blank A solution used in photometry/spectrophotometry that is identical to calibrating or unknown solutions except for the substance to be measured.

Blastocyst A thin-walled hollow structure in early embryonic development that contains a cluster of cells called the inner cell mass from which the embryo arises.

Blood gases The partial pressures of carbon dioxide (PCO_2) and oxygen (PO_2) measured in whole blood.

Blood group antigen Antigen containing a major carbohydrate component usually found on the surface of cells or secreted by cells.

Bone alkaline phosphatase (BALP) An isoenzyme of alkaline phosphatase found in bone and a biochemical marker of bone formation.

Bowman capsule T e double-walled globular kidney structure that forms the beginning of a renal tubule and surrounds the glomerulus.

Branched-chain signal amplification A molecular probe technique that utilizes branched DNA (bDNA) as a means to amplify the hybridization signal.

Breath tests Tests that detect products of bacterial metabolism in the gut or products of human metabolism by measuring, most commonly, CO_2 and H_2 in the breath.

Buffer solution A solution containing either a weak acid and its salt or a weak base and its salt, which is resistant to changes in pH.

BUN (blood urea nitrogen) Obsolete term used to report results of a urea assay, particularly in the United States.

Calcitonin A 32-amino-acid polypeptide hormone elaborated by the parafollicular cells of the thyroid gland in response to hypercalcemia.

Calibration In relation to analytical methods, a function that describes the relationship between instrument signal and concentration of analyte.

Cancer A relative autonomous growth of tissue.

Cancer staging T e process by which cancer is divided into groups of early and late disease; useful for prognosis and for guiding therapy.

Capillary electrophoresis A method in which the classic techniques of electrophoresis are carried out in a small-bore, fused silica capillary tube coated with a polymeric covering.

Carbohydrate Aldehyde or ketone derivatives of polyhydroxy alcohols composed of carbon, hydrogen, and oxygen in a ratio of 1:2:1.

Carbohydrate markers Carbohydrate-related tumor markers may be (1) antigens on the tumor cell surface or (2) secreted by the tumor cells.

Carboxyhemoglobin A form of hemoglobin in which the sites usually bound to oxygen are bound to carbon monoxide.

Carcinoembryonic antigen (CEA) A glycoprotein secreted into the glycocalyx coating the luminal surface of gastrointestinal epithelia.

Carcinogen Any cancer-producing substance.

Carcinoid syndrome A syndrome due to carcinoid tumors and characterized by attacks of severe cyanotic flushing of the skin—lasting from minutes to days—and by diarrheal watery stools, bronchoconstrictive attacks, sudden drops in blood pressure, edema, and ascites. Symptoms are caused by secretion from the tumor of serotonin, prostaglandins, and other biologically active substances.

Carcinoid tumor A yellow circumscribed tumor arising from enterochromaf n cells, usually in the small intestine, appendix, stomach, or colon, and less commonly in the bronchus; sometimes used alone to refer to the gastrointestinal tumor (called also argentaf noma).

Carcinoma A malignant new growth made up of epithelial cells tending to infiltrate the surrounding tissues and give rise to metastases.

Cardiac biomarker A biological compound whose measurement is useful in the diagnosis of cardiac disease; used to (1) detect cardiac disorders, (2) detect risk of developing cardiac disorders, (3) monitor the disorder, or (4) predict the response of a disorder to a treatment.

Cardiomyopathy A general diagnostic term designating primary noninflammatory disease of the heart muscle.

Carry-over T e transport of a quantity of analyte or reagent from one specimen reaction into and contaminating a subsequent one.

Catalyst A substance that modifies and increases the rate of a chemical reaction without being permanently changed or consumed; an enzyme is a protein catalyst of biological origin.

Catecholamine One of a group of biogenic amines having a sympathomimetic action, the aromatic portion of whose molecule is catechol, and the aliphatic portion an amine; examples include dopamine, norepinephrine, and epinephrine.

Catecholamine metabolites Products of catecholamine metabolism, such as dihydroxyphenylacetic acid, methoxytyramine, homovanillic acid, dihydroxyphenylglycol, methoxyhydroxyphenylglycol, normetanephrine, metanephrine, and vanillylmandelic acid.

Catechol-O-methyltransferase (COMT) An enzyme that degrades catecholamines.

Celiac disease A disease caused by the destructive interaction of gluten with the intestinal mucosa causing malabsorption. In most cases, the mucosal damage is reversed by withdrawing all gluten-containing foods from the diet. Also called gluten-sensitive enteropathy.

CentiMorgan (cM) A unit of measure that refers to the distance between two gene loci determined by the frequency

with which recombination occurs between them. Two loci are said to be one cM apart if recombination is observed between them in 1% of cell division cycles.

Central hypothyroidism Refers to thyroid hormone deficiency due to a disorder of the (1) pituitary, (2) hypothalamus, or (3) hypothalamic-pituitary portal circulation.

Centrifugation T e process of using centrifugal force to separate the lighter portions of a solution from the heavier portions; a centrifuge is a device by which centrifugation is effected.

Centromere A primary constriction in a chromosome; centromeres play an important role in directing the movement of chromosomes between daughter cells during cell division.

CERCLA Comprehensive Environmental Response, Compensation, and Liability Act.

Chelation therapy Administration of chelating agents to remove metals from the body.

Chemical hygiene plan (CHP) An Occupational Safety and Health Administration (OSHA)-required listing of responsibilities for laboratory employers, employees, and a chemical hygiene of cer, and including a complete chemical inventory that is updated annually, along with a copy of the Material Safety Data Sheet (MSDS) that defines each chemical as toxic, carcinogenic, or dangerous, and that must be on file and available to all employees 24 hours a day, 7 days a week.

Chemical speciation Refers to the molecular form of atoms of an element or a cluster of atoms of different elements in a given matrix.

Chemiluminescence T e emission of light when an electron returns from an excited or higher energy level to a lower energy level, in which the excitation event is caused by a chemical reaction and not by photo illumination; the excitation event is caused by the oxidation of an organic compound.

Chemosensor A sensor design in a point-of-care testing device that detects intrinsic properties of an analyte or that is combined with a transducing element to detect signals produced by the analyte binding to some indicator.

Cholecystitis A painful inflammation of the gallbladder.

Cholecystokinin (CCK) A 33-amino-acid peptide secreted by the upper intestinal mucosa and also found in the central nervous system. It causes gallbladder contraction and release of pancreatic exocrine (or digestive) enzymes, and affects other gastrointestinal (GI) functions.

Cholestasis of pregnancy A condition during pregnancy characterized by impaired bile flow allowing bile salts to be deposited in the skin and the placenta.

Cholestasis Suppression of the normal flow of bile.

Cholesterol A steroid alcohol with 27 carbon atoms that are arranged in a tetracyclical sterane ring system, with a C-H side chain and a polar hydroxyl group on its A-ring, making it an amphipathic molecule.

Cholinergic toxidrome A toxidrome that represents the acute phase of cholinesterase inhibitor poisoning.

Cholinesterase An enzyme of the hydrolase class that catalyzes the cleavage of the acyl group from various esters of choline, including acetylcholine, and some related compounds.

Chorionic villi One of the minute vascular projections of the fetal chorion that combines with maternal uterine tissue to form the placenta.

Chorionic villus sampling A prenatal test to detect birth defects that is performed at an early stage of pregnancy and involves retrieval and examination of tissue from the chorionic villi. Also called chorionic villus biopsy.

Chromaffin cell Neuroendocrine cell derived from embryonic neural crest found in the medulla of the adrenal gland and in other ganglia of the sympathetic nervous system; so-named because of the presence of cytoplasmic granules that give a brownish reaction with chromium salts.

Chromatin Nuclear DNA and its associated structural proteins; chromatin is arranged and organized in a hierarchical fashion in which the degree of its condensation increases with higher levels of structural organization.

Chromatogram A plot of detector response as a function of time or mobile phase volume.

Chromatography A group of separation techniques that separate analytes by differential distribution between a stationary phase and a mobile phase.

Chromosome A highly ordered structure of a single double-stranded DNA (dsDNA) molecule, compacted many times with the aid of structural DNA-binding proteins.

Chronic hepatitis A collective term for a clinical and pathological syndrome that has several causes and is characterized by varying degrees of hepatocellular necrosis and inflammation for at least 6 months.

Chronic kidney disease (CKD) Abnormalities of kidney structure or function, present for greater than 3 months, with implications for health.

Chronic myelocytic leukemia (CML) Chronic leukemia characterized by granular leukocytes.

Chronic obstructive pulmonary disease (COPD) Any disorder characterized by persistent or recurring obstruction of bronchial air flow, such as chronic bronchitis, asthma, or pulmonary emphysema.

Chronic pancreatitis An inflammatory disease characterized by persistent and progressive destruction of the pancreas.

Chyme Food that has been acted upon by the churning action of the stomach and by stomach juices and expelled by the stomach into the duodenum.

Circadian rhythms Rhythmic repetition of certain phenomena in living organisms at about the same time each day.

Cirrhosis Liver disease characterized pathologically by loss of the normal microscopic lobular architecture with fibrosis and nodular regeneration.

Citrullinemia type II An autosomal recessive disease characterized by increased concentrations of citrulline in serum and urine. Ammonia intoxication is another manifestation. T is disorder is characterized by neuropsychiatric symptoms, including abnormal behaviors, loss of memory, seizures, and coma.

CLIA waived tests Tests categorized as "waived" by the FDA under the Clinical Laboratory Improvement Amendments of 1988. T ese tests employ methodologies that are

considered to be so simple and accurate as to render the likelihood of erroneous results negligible.

Clinical audit A review of case histories of patients against the benchmark of current best practice; used as a tool to improve clinical practice.

Clinical enzymology The branch of medical science that deals with the biochemical nature and activity of enzymes of clinical relevance.

Clinical Laboratory Improvement Amendments of 1988 (CLIA-88) United States federal regulatory standards that apply to all clinical laboratory testing performed on humans in the United States, except clinical trials and basic research.

Clinical practice guidelines Systematically developed statements to assist practitioner and patient decisions about appropriate healthcare for specific clinical circumstances; in the laboratory, goals for accuracy, precision, and turnaround times of tests are included.

Clinical reference standard The best available method for establishing the presence or absence of the target condition; also, the suspected condition or disease for which the target is to be applied.

Clinical sensitivity The proportion of subjects with disease who have positive test results.

Clinical specificity The proportion of subjects without disease who have negative test results.

Clinical toxicology A subdivision of toxicology that involves the analysis of drugs, heavy metals, and other chemical agents in body fluids and tissues for the purpose of patient care.

Cloning In biology, cloning is the process of producing similar populations of genetically identical individuals. In molecular diagnostics, cloning is the process used to create copies of DNA fragments (molecular cloning), cells (cell cloning), or organisms.

CLSI The Clinical and Laboratory Standards Institute (formerly the National Committee for Clinical Laboratory Standards, or NCCLS) that guides the development and implementation of standards and guidelines that help all laboratories fulfill their goals.

Coagulation (clotting) The sequential process by which the multiple coagulation factors of blood interact in the coagulation cascade, resulting in formation of an insoluble fibrin clot.

Cocaine A crystalline alkaloid, obtained from leaves of Erythroxylon coca (coca leaves) and other Erythroxylon species, or by synthesis from ecgonine or its derivatives.

Codon A three-nucleotide sequence that "codes" for an amino acid during translation; there are 64 possible codons in nuclear DNA.

Coenzyme An organic nonprotein molecule that binds with the protein molecule (apoenzyme) to form the active enzyme (holoenzyme).

Cofactor A natural reactant, usually a metal ion or a coenzyme, that is required in an enzyme-catalyzed reaction.

Colligative properties Properties of solutions that depend on the number of particles in the solution; examples include (1) osmotic pressure, (2) boiling point elevation, (3) freezing point depression, and (4) vapor pressure lowering.

Colloid An amorphous material found in the follicular lumen of the thyroid gland. A critical component is thyroglobulin (Tg).

Column chromatography A separation method in which the stationary phase is packed into a tube or is coated onto the inner surface of the tube.

Column packing Particulate matter packed into a column used for chromatographic techniques.

Commutability The equivalence of the mathematical relationships between the results of different measurement procedures for a reference material and for representative samples from healthy and diseased individuals.

Comparative genomic hybridization A cytogenetic technique in which reference and test DNA are respectively labeled with green- and red-fluorescing fluorochromes. Genetic abnormalities are detected by changes in the green-to-red ratio.

Compensated metabolic acidosis A state of acidosis in which the pH of the blood has been returned toward normal by respiratory compensation.

Competitive immunoassay An immunoassay in which all reactants are simultaneously or sequentially mixed together and unlabeled antigen competes with labeled antigen for binding sites on the antibody; no separation step is included in this assay.

Complement system Complex system of proteins found in blood that combines with antibodies to destroy pathogenic bacteria and other foreign cells.

Complete blood count (CBC) The determination of the quantity of each type of blood cell in a mL of blood, often including the amount of hemoglobin, the hematocrit, and the proportions of various white cells.

Conception The union of the sperm and the ovum. Synonymous with fertilization.

Conductometry An electrochemical technique used to determine the quantity of an analyte present in a mixture by measuring its effect on the electrical conductivity of the mixture.

Confirmatory testing As used in programs that test for drugs of abuse, confirmatory tests are used to confirm a positive or sometimes negative result that had been presumptively classified as positive for a specific drug.

Conformation-sensitive gel electrophoresis (CSGE) A type of electrophoretic mutation scanning in which a segment of DNA is screened for mismatch pairing between normal and mutated base pairs.

Congenital adrenal hyperplasia (CAH) A group of inherited disorders in which deficiencies of enzymes that catalyze the biosynthesis of cortisol result in compensatory hypersecretion of corticotropin and subsequent adrenal hyperplasia as well as excessive androgen production.

Congenital erythropoietic porphyria (CEP) An autosomal recessive porphyria due to mutation in the UROS gene (locus: 10q25.2-q26.3), which encodes uroporphyrinogen-III synthase.

Congenital hypothyroidism A pathological condition resulting from severe thyroid insuf ciency, which may lead to cretinism or myxedema.

Congestive heart failure (CHF) or heart failure A clinical syndrome due to heart disease, characterized by breathlessness and abnormal sodium and water retention, often resulting in edema.

Conjugated bilirubin Bilirubin that has been taken up by the liver cells and conjugated to form the water-soluble bilirubin diglucuronide.

Conn syndrome A condition of primary aldosteronism arising from oversecretion of aldosterone by an adrenal cortical adenoma.

Connectivity In a clinical laboratory, the linking of an analytical device via an electronic interface to a laboratory information system computer.

Continuous ambulatory peritoneal dialysis (CAPD) A common method of peritoneal dialysis, involving the continuous presence of dialysis solution in the peritoneal cavity.

Continuous-flow analysis Type of analysis in which each specimen in a batch passes through the same continuous stream at the same rate and is subjected to the same analytical reactions.

Control procedure Statistical and/or nonstatistical check protocols implemented in a clinical laboratory to assess the performance of an analytical method.

Control rules Decision criteria that define when an analytical run is judged acceptable ("in control") or unacceptable ("out of control").

Coproporphyrin A porphyrin with four methyl and four propionic acid sidechains attached to the tetrapyrrole backbone.

Copy number variant (CNV) A structural variant of a large region of the genome that has been deleted or duplicated.

Core laboratory A laboratory that provides all of the high-volume and emergency testing in many hospitals.

Cori cycle T e mechanism by which lactate produced by muscles is carried to the liver, converted back to glucose via gluconeogenesis, and returned to the muscles.

Coronary arteries T e two main arteries that provide blood to the heart, surrounding the heart like a crown, coming out of the aorta, arching down over the top of the heart, and dividing into two branches.

Coronary heart disease A narrowing of the small blood vessels that supply blood and oxygen to the heart.

Corpus luteum A yellow glandular mass in the ovary formed by an ovarian follicle that has matured and discharged its ovum; secretes progesterone.

Corticosteroid-binding globulin (transcortin) An α-globulin that binds unconjugated corticosteroid and transports it in the plasma.

Corticotropin-releasing hormone (CRH) A neuropeptide released by the hypothalamus that stimulates release of ACTH (corticotropin) by the anterior pituitary gland.

Cortisol T e major adrenal glucocorticoid synthesized in the zona fasciculata (and, to a lesser extent, the zona reticularis) of the adrenal cortex.

Coulometry An electrochemical technique that measures the electrical charge passing between two electrodes in an electrochemical cell, with the amount of charge passing between the electrodes being directly proportional to oxidation or reduction of an electroactive substance at one of the electrodes.

C-Peptide A 31-amino-acid protein that connects insulin's A-chain to its B-chain in the proinsulin molecule.

Crack cocaine T e freebase form of cocaine that can be smoked.

Creatine kinase A dimeric transferase enzyme that catalyzes the reversible phosphorylation of creatine by ATP. CK has four forms: CK-MM, CK-MB, CK-BB, and mitochondrial CK.

Creatinine A nonprotein nitrogen compound derived from the spontaneous hydrolysis of creatine or the cyclization of phosphocreatine; creatinine production is relatively constant, is related to muscle mass, and is often used as a marker of the glomerular filtration rate of the kidneys.

Cretinism An archaic term for the clinical consequences of untreated congenital hypothyroidism caused by a deficiency of thyroid hormone during prenatal development and infancy; characterized in childhood by short stature, developmental delay, dystrophy of the bones, and a low basal metabolism. Also called congenital myxedema, which is also an archaic term.

Crigler-Najjar syndrome An autosomal recessive form of nonhemolytic jaundice due to the absence of the hepatic enzyme glucuronosyltransferase.

Crohn disease A chronic inflammatory disease that may affect any part of the intestine from the mouth to the anus.

CTx An antigen produced when type I collagen is digested by the proteinase cathepsin K yielding cross-linked carboxy-terminal telopeptide of type I collagen; a serum marker for bone resorption and action of cathepsin K.

Cushing disease A condition characterized by hyperadrenocorticism that is secondary to excessive anterior pituitary secretion of corticotropin by the pituitary.

Cushing syndrome A condition characterized by an increased concentration of adrenal glucocorticoid hormone in the bloodstream and its effects on the body.

Cutaneous porphyrias Disorders of heme biosynthesis in which accumulations of porphyrins in the skin cause skin damage on exposure to sunlight.

Cyclic adenosine monophosphate (cAMP) A cyclic nucleotide that serves as an intracellular and, in some cases, extracellular "second messenger" mediating the action of many peptide or amine hormones.

Cystic fibrosis (CF) An inherited disease caused by genetic alteration of a cystic fibrosis transmembrane conductance regulator (CFTR) protein that leads to chronic pancreatic and obstructive pulmonary disease.

Cystic fibrosis transmembrane conductance regulator (CFTR) A transmembrane protein produced by the CFTR gene.

Cytochrome P_{450} (CYP) A large family of metabolic enzymes that catalyze the oxidations of organic substrates. T ey are

important in metabolism of drugs, steroid hormones, fatty acids, and other substances. Note: Often abbreviated as CYP usually followed by an arabic numeral, a letter, and another arabic numeral (e.g., CYP 2D6).

Cytokeratin One of the two types of keratin normally found in human tissue, constituting a group of proteins; these are normally found in keratin filaments.

Dehydroepiandrosterone (DHEA) A hormone produced by the adrenal glands. After being secreted, it circulates in the bloodstream as DHEA-sulfate (DHEAS) and is converted as needed into other hormones. It is the major androgen precursor in females.

Deletion A DNA sequence that is missing in one sample compared with another. Deletions may be as small as one nucleotide or as large as an entire chromosome.

Denaturing gradient gel electrophoresis (DGGE) An electrophoretic method for separating DNA fragments according to their mobilities under increasing denaturing conditions (usually increasing formamide or urea concentrations).

Densitometry A measuring technique that uses an optical system to scan and quantify electrophoretic fractions separated on a gel or other medium.

Dent disease Tubulopathy of the proximal renal tubules with low molecular weight proteinuria, hypercalciuria, hypokalemia, nephrocalcinosis, rickets, and progressive renal failure.

Deoxypyridinoline (DPD) A deoxypyridinoline crosslink of type I collagen present in bone that is excreted, free or protein-bound, in urine and serves as a marker of bone resorption.

Deoxyribonucleic acid (DNA) A nucleic acid that carries the genetic information in the cell. It consists of two long chains of nucleotides twisted into a double helix and joined by hydrogen bonds between the complementary bases adenine and thymine or cytosine and guanine. The sequence of nucleotides determines individual hereditary characteristics.

Deoxyribonucleotide triphosphates (dNDT) The building blocks of DNA (typically dATP, dCTP, dGTP, and dTTP).

Depletional hyponatremia A condition characterized by low plasma concentration of sodium associated with low total body sodium and normal blood volume; called also euvolemic hyponatremia.

Derivatization Labeling of or chemical addition to an analyte performed to increase the column retention or detectability of that analyte.

Detection methods In molecular diagnostics, these are the techniques used to detect nucleic acid sequences, usually after purification and amplification.

Detector A device that responds to the presence of analyte in the mobile phase, the magnitude of which is used to identify and quantify analytes; universal units detect most analytes and selective devices detect only analytes with specific properties.

Diabetes Control and Complications Trial (DCCT) A medical study of diabetic patients conducted in the United States and Canada in 1983-1993 by the National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK).

Diabetes insipidus Any of several types of polyuria in which the volume of urine exceeds 3 liters per day, causing dehydration and great thirst, as well as sometimes emaciation and great hunger. Caused by either a deficiency of ADH or defective receptor action.

Diabetes mellitus A group of metabolic disorders of carbohydrate metabolism in which glucose is underutilized, producing hyperglycemia.

Diabetic nephropathy The nephropathy that commonly accompanies later stages of diabetes mellitus. It begins with hyperfiltration, renal hypertrophy, albuminuria, and hypertension.

Diabetic retinopathy The retinal changes associated with diabetes mellitus.

Diabetogenes Genes that contribute to the development of diabetes; a genetic basis is identified in less than 5% of individuals with type 2 diabetes.

Diagnostic accuracy The closeness of agreement between values obtained from a diagnostic test (index test) and those of reference standard (gold standard) for a specific disease or condition; these results are expressed in a number of ways, including sensitivity and specificity, predictive values, likelihood ratios, diagnostic odds ratios, and areas under receiver operating characteristic (ROC) curves.

Dialysis The removal of certain elements from the blood by virtue of the difference in the rates of their diffusion through a semipermeable membrane, for example, by means of a hemodialysis (HD) machine or filter.

Diarrhea The passage of loose or liquid stools more than three times daily and/or a stool weight greater than 200 g/day.

Dideoxy-termination sequencing A method of DNA sequencing based on the selective incorporation of chain-terminating dideoxynucleotides by DNA polymerase during in vitro DNA replication. Also known as Sanger sequencing.

Difference plot A bias plot that shows the dispersion of observed differences between the measurements of two methods as a function of the average concentration of the measurements; also referred to as a "Bland-Altman plot."

Digestion The conversion of food, in the stomach and intestines, into soluble and diffusible products, capable of being absorbed.

Digestive process A three-phase process—neurogenic, gastric, and intestinal. The neurogenic (vagal) phase is initiated by the sight, smell, and taste of food. The gastric phase is initiated by the distention of the stomach by the entry of food. The intestinal phase begins when the partly digested food enters the duodenum from the stomach.

Digital Polymerase Chain Reaction A modification of conventional PCR where the sample is separated into a large number of partitions and the amplification is carried out in each partition individually. Also known as dPCR.

Digital rectal examination (DRE) A technique used for the early detection of prostate cancer. It is performed by inserting a gloved, lubricated finger into the rectum and feeling for abnormalities.

Dihydropteridine reductase (DHPR) An enzyme that catalyzes the reversible formation of tetrahydrobiopterin (BH_4) from dihydrobiopterine; deficiency of BH_4 results in malignant hyperphenylalaninemia.

Dihydrotestosterone (DHT) A powerful androgenic hormone that is formed in peripheral tissue by the action of the enzyme 5α-reductase on testosterone.

3,4-Dihydroxyphenylglycol (DHPG) The metabolite produced within the peripheral sympathetic or central nervous system noradrenergic nerves by deamination of norepinephrine (can also be formed from epinephrine); O-methylated to methoxyhydroxyphenylglycol in extraneuronal tissues.

Dilutional hyponatremia A condition characterized by low plasma concentration of sodium resulting from loss of sodium from the body with nonosmotic retention of water.

Dipsticks Single- or multi-pad measurement devices that quantify from one to several analytes.

Direct bilirubin The fraction of bilirubin that reacts with the diazo reagent in the absence of alcohol.

Discrete analysis Type of analysis in which the sample is aspirated into the sample probe and then is delivered, often with reagent, through the same orifice into a reaction cup or another container.

Disorders of amino acid metabolism A group of disorders of amino acid metabolism caused by defective activity of an enzyme leading to increased amino acids in blood (and urine).

Disorders of carbohydrate metabolism A group of disorders caused by loss of an enzyme in the metabolic pathway of a carbohydrate, leading to increased concentrations of that carbohydrate in blood or its accumulation within organs and tissues.

Disorders of fatty acid oxidation A group of disorders caused by deficiency of an enzyme in the oxidation pathway of fatty acids, leading to inability to use fat as an energy source.

Diuresis Increased excretion of urine.

Diurnal variation Variation that occurs in the amount of a substance during a 24-hour period.

DNA methylation The addition of a methyl group typically to the fifth carbon position of cytosine residues in CpG dinucleotides; this epigenetic process is implicated in growth and development of organisms.

DNA methyltransferase (DNMT) Any of a group of enzymes that catalyze the transfer of a methyl group from S-adenosylmethionine to a specific nucleotide in a DNA molecule, with different enzymes acting on specific nucleotides and positions of methylation.

DNA microarray An array of microscopic spots of different DNA molecules attached to a solid surface. Also known as DNA chip or biochip.

DNA-binding proteins Proteins that recognize and bind to specific DNA sequences. Some DNA-binding proteins are involved in the regulation of DNA transcription.

Dopamine A catecholamine formed in the body by the decarboxylation of l-dopa; an intermediate product in the synthesis of norepinephrine; acts as a neurotransmitter in the central nervous system, produced peripherally and acts on peripheral receptors.

Dot blotting A blotting technique in which the biomolecules to be detected are applied directly on a membrane as dots.

Down syndrome A birth defect characterized by having three copies of chromosome 21 rather than the normal two copies. Also known as trisomy 21.

Dried blood spot (DBS) A form of biosampling where blood samples are blotted and dried on filter paper.

Drosha A Class 2 RNase III enzyme responsible for processing of microRNA (miRNA).

Drug facilitated sexual assault (DFSA) The use of (1) alcohol, (2) drugs, and/or (3) chemical agents to incapacitate an individual and facilitate sexual assault.

Drug half-life Time required for one-half of an administered drug to be lost through metabolism and elimination.

Drug interactions The effects of a drug on absorption, metabolism, or action of another drug.

Drug metabolism The process by which drugs are chemically modified in the body.

Drug monitoring The process of studying the effects of a chemical substance administered to an individual.

Drug-induced liver injury (DILI) Damage to the liver that is caused by prescribed medications, over-the-counter medications, vitamins, hormones, herbs, illicit ("recreational") drugs, and environmental toxins.

Drugs of abuse Drugs that are repeatedly and deliberately used in a way other than prescribed or socially sanctioned (i.e., a drug that is taken for nonmedicinal reasons).

Dubin–Johnson syndrome An autosomal recessive disorder that causes an increase of conjugated bilirubin in the serum.

Dumping syndrome Following gastric surgery, hyperosmolar chyme is "dumped" into the small intestine causing rapid hypovolemia and hemoconcentration.

Eclampsia Convulsions and coma occurring in a pregnant woman or a woman who recently gave birth.

Ectopic pregnancy An embryo developing in the fallopian tube or abdomen instead of the uterus.

Ectopic syndrome Production of a hormone by nonendocrine cancerous tissue that normally does not produce the hormone (e.g., ACTH production by small-cell lung carcinoma).

Electrocardiogram (ECG) A graphic recording of the electrical activity produced by the heart.

Electrochemical cell An electrochemical device that consists of two electrodes (electron or metallic conductors) that are connected by an electrolyte solution that conducts ions (galvanic cell), or an electrochemical device in which an external voltage is applied to a polarizable working electrode with the resulting cathodic or anodic current of the cell being monitored (electrolytic cell).

Electrochemiluminescence The emission of light when an electron returns from an excited or higher energy level to a lower energy level, in which the excitation event is a reaction generated electrochemically on the surface of an electrode.

Electrode A half-cell that consists of a single metallic conductor in contact with an electrolyte solution; the indicator (measuring) electrode is one half-cell and the reference electrode is the second half-cell.

Electrode potential The reduction potential for a redox couple that is measured with respect to a standard hydrogen electrode set at zero; the electromotive force of an electrochemical cell.

Electrolyte exclusion effect Electrolytes are excluded from the fraction of total plasma volume that is occupied by solids, which leads to underestimation of electrolyte concentration by some methods.

Electrolytes Charged low-molecular-mass molecules present in plasma and cytosol, usually ions of (1) sodium, (2) potassium, (3) calcium, (4) magnesium, (5) chloride, (6) bicarbonate, (7) phosphate, (8) sulfate, and (9) lactate.

Electropherogram A densitometric display of protein zones on a support material after separation and staining.

Electrophoresis The migration of charged solutes or particles within a liquid medium under the influence of an electrical field.

Electrophoretic mobility (μ) The rate of migration (cm/s) of a charged solute in an electrical field, expressed per unit field strength (volts/cm).

Electrospray ionization A commonly used technique in which a sample is ionized at atmospheric pressure before introduction into the mass analyzer.

Embryo A developing infant that has not yet finished organ development (before 10 weeks gestation).

Enantiomer A molecule that exhibits stereoisomerism through the presence of one or more chiral centers (i.e., stereoisomers that are nonsuperimposable mirror images).

Endocrine system The system of glands that release their secretions (hormones) directly into the circulatory system. In addition to the endocrine glands, included are the chromaffin and the neurosecretory systems.

Endocrinology The scientific study of the function and pathology of the endocrine glands.

Endometrium The glandular mucous membrane that lines the uterus.

Endonuclease An enzyme that hydrolyzes an internal phosphodiester bond, splitting a nucleic acid into two or more parts.

Endosmosis (electroendosmotic flow) Preferential movement of water in one direction through an electrophoresis medium due to selective binding of one type of charge on the surface of the medium.

End-stage renal disease (ESRD) A condition where renal function is inadequate to support life.

Enteric nervous system (ENS) An independent and integrated system of neurons and supporting cells.

Enzyme A protein with catalytic properties.

Enzyme induction Increased synthesis of an enzyme in response to an inducer or other stimulus.

Enzyme inhibition Decreased enzymatic activity due to substrate competition or the presence of a compound that reduces enzyme function.

Epigenetics Processes that alter gene function or its interpretation by mechanisms other than those that rely on changes in DNA sequences; these processes include DNA methylation, genomic imprinting, histone modification, and chromatin remodeling.

Epinephrine (adrenaline) A catecholamine hormone secreted by the adrenal medulla.

Ergonomics The study of capabilities in relationship to work demands completed by defining postures that minimize unnecessary static work and reduce the forces working on the body.

Erythropoietic protoporphyria (EPP) An autosomal dominant disorder due to mutation in the FECH gene (locus: 18q21.3), which encodes ferrochelatase, causing a partial deficiency of the enzyme.

Erythropoietin A glycoprotein hormone secreted chiefly by the kidney in the adult; it increases the production of red blood cells.

Essential amino acids Amino acids that are not synthesized by humans and therefore are essential dietary constituents for maintaining health or growth.

Essential nutrients Nutrients (proteins, minerals, carbohydrates, lipids, vitamins) necessary for growth, normal functioning, and maintenance of life; they must be supplied by food because they cannot be synthesized by the body.

Estimated average requirement (EAR) The daily intake of a specific nutrient estimated to meet the requirement in 50% of healthy people in an age- and gender-specific group. The EAR is used to calculate the recommended dietary allowance.

Estradiol (E_2) and Estriol (E_3) Estrogenic hormones produced by the (1) ovaries, (2) corpus luteum, and during pregnancy by the (3) placenta. The adrenal glands and testes (in men) are also believed to secrete smaller quantities of estrogens.

Estrone (E_1) A natural estrogenic hormone that is a ketone found in the body chiefly as a metabolite of estradiol (E_2); it is also secreted especially by the ovaries.

Ethics Rules or standards governing the conduct of an individual or the members of a profession.

Ethylene glycol An ethylene compound with two hydroxy groups located on adjacent carbons. It is a common ingredient in antifreeze and is highly toxic if ingested.

Euchromatin Genomic regions that are rich in genes and are, in general, less compactly organized during interphase.

Eukaryote Organisms such as higher plants and animals, fungi, protozoa, and most algae; they have a true nucleus bounded by a nuclear membrane within which lie the chromosomes.

Euthyroid Having normal thyroid function.

Euthyroid hyperthyroxinemia A condition characterized by increased concentrations of thyroxine in the blood but a normal concentration of thyroid-stimulating hormone and normal thyroid function.

Evidence-based laboratory medicine The application of principles and techniques of evidence-based medicine to laboratory medicine; the conscientious, judicious, and explicit use of best evidence in laboratory medicine investigations to assist decision making about the care of individual patients.

Evidence-based medicine T e conscientious, judicious, and explicit use of best evidence in making decisions about the care of individual patients.

Exome T e part of the genome that codes for exons, the sequences that remain in the mature RNA after transcription and removal of introns by RNA splicing. It differs from a transcriptome in that it consists of only DNA that is transcribed into mature RNA, excluding transfer RNA, ribosomal RNA, and other non-coding RNA.

Exon T e coding region of a gene that will be expressed as protein following translation.

Exonuclease A nuclease that releases one nucleotide at a time (serially) beginning at one end of a nucleic acid; exonuclease activity excises incorrectly paired nucleotides during replication.

Expected date of confinement (EDC) T e date at which an infant is expected to be born, calculated from the date of the last menstrual period (LMP). Also called due date.

Exposure control plan An Occupational Safety and Health Administration (OSHA)-required plan that ensures the protection of laboratory workers against potential exposure to bloodborne pathogens, while ensuring that medical wastes produced by the clinical laboratory are managed and handled in a safe and effective manner.

External quality assessment Procedures and programs that provide information about systematic errors and maintenance of long-term accuracy of analytical methods.

Extracellular fluid (ECF) A general term for all the body fluids outside the cells, including the interstitial fluid, plasma, lymph, and cerebrospinal fluid (CSF); this fluid provides a constant external environment for the cells.

Extracted ion profile T e sum of ions over a limited m/z ranged displayed as a function of time.

Facilitative glucose transporters A group of membrane proteins that facilitate the transport of glucose over a plasma membrane.

Familial hypophosphatemic rickets Any of several inherited disorders of proximal renal tubular function causing phosphate loss, hypophosphatemia, and skeletal deformities, including rickets and osteomalacia.

Fanconi syndrome A rare recessive disorder with a poor prognosis, characterized by pancytopenia, bone marrow hypoplasia, and patchy brown skin and multiple congenital anomalies of the musculoskeletal and genitourinary systems.

Fasting Abstinence from all food and drink except water for a prescribed period.

Fatty acid Any straight-chain monocarboxylic acid with an alkyl chain generally classed as saturated fatty acids with no double bonds; monounsaturated fatty acids with one double bond; and polyunsaturated fatty acids—those with multiple double bonds.

Female athletic triad A group of findings commonly seen in young female athletes, consisting of (1) eating disorders, (2) amenorrhea, and (3) osteoporosis.

Ferritin T e iron/apoferritin complex, which is one of the chief forms in which iron is stored in the body; it occurs in the (1) gastrointestinal mucosa, (2) liver, (3) spleen, (4) bone marrow, and (5) reticuloendothelial cells.

Ferrochelatase A mitochondrial enzyme of the lyase class that catalyzes the insertion of ferrous iron into protoporphyrin IX to form protoheme IX, the heme of hemoglobin.

Fetal erythroblastosis A severe hemolytic disease of a fetus or newborn infant caused by the production of maternal antibodies against the fetal red blood cells, usually involving rhesus (Rh) blood group incompatibility between the mother and fetus.

Fetal fibronectin (fFN) A protein produced during pregnancy that is thought to function as a "glue" attaching the fetal sac to the uterine lining; a test for fFN in cervicovaginal fluid is used to assess risk of preterm labor.

Fetal lung maturity (FLM) A test that estimates the likelihood a neonate will develop respiratory distress syndrome.

Fetus A developing infant that has finished organ development (following 10 weeks gestation).

First messenger A factor or hormone that binds to a receptor on the external surface of a cell and sets off a series of reactions that eventually convert a precursor into a second messenger.

First-order kinetics In an enzymatic reaction, a phase of first-order dependence on substrate concentration when the rate of the reaction is proportional to the concentration of substrate or when the enzyme concentration is fixed and the substrate concentration is varied.

First-pass metabolism Extensive hepatic metabolism of a drug before it reaches the systemic circulation.

Flow cytometry T e measurement of a physical or chemical characteristic of cells or particles made while the cells or particles pass singly through a measuring apparatus in a flowing fluid stream.

Fluorescence A physical property of some molecules to emit light at a longer wavelength when excited at a shorter wavelength.

Fluorescence in situ hybridization (FISH) An in situ hybridization technique in which DNA probes are labeled with fluorescent tags and hybridized to DNA to identify and localize specific sequences. Chromosome painting is a form of FISH.

Fluorescence T e emission of electromagnetic radiation that occurs when a molecule absorbs light at one wavelength and reemits light at a longer wavelength, when it returns to ground state with the excitation event being caused by photo illumination.

Fluorometry T e measurement of emitted fluorescence light that occurs when a molecule absorbs light at one wavelength and reemits light at a longer wavelength.

Follicle A pouch-like sac that is on the surface of the ovary and contains the maturing ovum (egg); also called Graafian follicle.

Follicle-stimulating hormone (FSH) An anterior pituitary peptide that stimulates the development of Graafian follicles in the female and spermatozoa in the male.

Fragment ion An ion formed by dissociation of a molecular ion, by convention often limited to fragmentation prior to mass analysis.

Fulminant hepatic failure A condition characterized by the development of severe liver injury with impaired synthetic capacity and encephalopathy in patients with previous normal liver or at least well-compensated liver disease.

Fulminant hepatitis A rare and frequently fatal form of acute hepatitis B in which the patient's condition rapidly deteriorates with hepatic encephalopathy, necrosis of the hepatic parenchyma, coagulopathy, renal failure, and coma.

Galactosemia An inherited disease in which the transformation of galactose to glucose is blocked, allowing galactose to increase to toxic concentrations in the body.

Gallstone A solid formation in the gallbladder, most commonly composed of cholesterol and bile salts.

Gamma-hydroxybutyrate (GHB) A potent sedative, hypnotic, euphorigenic agent that is illicitly ingested for its pleasurable effects.

Gas chromatography (GC) Column chromatography in which the mobile phase is a gas.

Gas chromatography-mass spectrometry (GC-MS) A combined technique in which a mixture of analytes is separated into individual components by gas chromatography, followed by the ionization of the separated compounds in the ion source of a mass spectrometer.

Gastrin A group of peptide hormones secreted by gastrointestinal (GI) mucosa cells in response to mechanical stress or high pH, both of which are produced by the presence of food in the stomach. Gastrin stimulates the stomach parietal cells to produce hydrochloric acid (HCl).

Gastrinoma A tumor of the pancreatic islet cells that results in an overproduction of gastric acid, leading to fulminant ulceration of the esophagus, stomach, duodenum, and jejunum. Gastrinoma may also occur in the stomach, duodenum, spleen, and regional lymph nodes.

Gastritis Mucosal inflammation of the stomach.

Gastroenteropancreatic neuroendocrine tumor (GEP-NET) Encompasses neuroendocrine tumors of the digestive system and pancreas but also covers neuroendocrine pulmonary tumors and includes carcinoid tumorss.

Gene A unit of DNA that specifies production of proteins and RNA molecules required for cellular function.

Gene duplication A process by which a chromosome or a portion of DNA is duplicated, resulting in an additional copy of a gene. Also referred to as chromosomal duplication or gene amplification.

Gene expression The process responsible for the flow of genetic information from gene to protein.

Generic form A drug not protected by a trademark. Also, the scientific name as opposed to the proprietary, brand name.

Genetic code The complete list of nucleotide codons and the amino acids or actions for which they "code."

Genetic Information Nondiscrimination Act of 2008 (GINA) Legislation enacted by the Congress of the United States that prohibits the use of genetic information in health insurance and employment.

Genome The complete set of chromosomes; the total complement of hereditary information; the human genome contains two copies, termed alleles, of each autosomal gene. One half of the genome is inherited from each parent and is termed the haploid genome. The complete genome inherited from both parents is termed the diploid genome.

Genotype The genetic makeup of an individual or a group of individuals. An individual's genotype codes for that individual's phenotype. The genotype for a specific gene requires knowledge of both alleles of the gene.

Genotyping Laboratory testing designed to detect specific genetic variants that are used to identify and classify variant alleles. The alleles are reported together as a genotype that may or may not be predictive of a phenotype.

Gestation The process, state or period of carrying an embryo or fetus from conception until birth; by convention, the time is measured clinically from the first day of the last menstrual period (LMP) and reported in weeks; gestational age of the fetus is often estimated by use of ultrasound.

Gestational diabetes mellitus (GDM) A condition of diabetes mellitus that sometimes occurs during pregnancy.

Ghrelin A peptide hormone, expressed primarily by the stomach, that stimulates the secretion of growth hormone and is considered a hunger-stimulating hormone.

Gilbert syndrome An inborn error of bilirubin metabolism.

Gitelman syndrome A syndrome of hypertrophy of juxtaglomerular cells similar to Bartter syndrome but with hypocalciuria and hypomagnesemia.

Gleason Score A grading system used to help evaluate the prognosis of men with prostate cancer.

Glioma A malignant tumor of the glial tissue of the nervous system.

Globulin Proteins that precipitate in water and redissolve when the salt concentration is raised.

Glomerular filtration rate (GFR) The rate in milliliters per minute at which small molecules are filtered through the kidney's glomeruli. It is a measure of the number of functioning nephrons.

Glomerulonephritis Nephritis accompanied by inflammation of the capillary loops of the glomeruli of the kidney. It occurs in acute, subacute, and chronic forms.

Glomerulus A tuft of blood vessels found in each nephron of the kidney that are involved in the filtration of the blood.

Glucagon A polypeptide hormone secreted by the alpha cells of the islets of Langerhans in response to hypoglycemia or the presence of acetylcholine, certain amino acids, or growth hormone. It helps to maintain blood glucose concentration by increasing blood glucose through glycogenolysis.

Glucocorticoids Any of the group of C21 steroids produced by the adrenal cortex that regulate carbohydrate, fat, and protein metabolism.

Glucose A six-carbon monosaccharide derived from the breakdown of carbohydrates in the diet or in body stores; also can be endogenously synthesized from protein or the glycerol moiety of triglyceride.

Glucose-dependent insulinotropic peptide (GIP, gastric inhibitory polypeptide) A peptide hormone (42 amino acids) that stimulates insulin release and at supraphysiological concentrations inhibits the release of gastric acid and pepsin.

Glucose-6-phosphate dehydrogenase (G-6-PD) deficiency An X-linked recessive hereditary disease characterized by abnormally low quantities of the enzyme G-6-PD involved in the pentose phosphate pathway, especially important in red blood cell metabolism.

Glucose tolerance test, oral (OGTT) A test whereby glucose is ingested into a fasting stomach and measurements of plasma glucose are taken over time; if glucose levels do not fall below specified cutpoints within 2 to 2.5 hours the patient may have impaired glucose tolerance or diabetes mellitus.

γ-Glutamyltransferase A transferase enzyme that reversibly catalyzes the transfer of a glutamyl group from a glutamyl-peptide and an amino acid to a peptide and a glutamyl-amino acid.

Glutaric acidemia type I (GAI) An inherited disorder in which an affected individual is unable to completely metabolize (1) lysine, (2) hydroxylysine, and (3) tryptophan. Excessive quantities of glutaric acid (GA) and related compounds accumulate and damage the brain.

Glycated hemoglobin Hemoglobin that has a sugar residue attached; HbA1c is the major fraction of glycated hemoglobin; also known as glycohemoglobin.

Glycogen An extensively branched polysaccharide containing many glucose residues and found particularly in muscle and liver cells for glucose storage.

Glycogen storage disease A group of rare inborn errors of metabolism caused by defects in specific enzymes or transporters involved in the metabolism of glycogen (also known as Von Gierke disease).

Goiter An enlargement of the thyroid gland that causes a swelling in the front part of the neck.

Gonad A gamete-producing organ (an ovary or a testis).

Gonadotropin Any hormone that stimulates the gonads.

Gonadotropin-releasing hormone (GnRH) A peptide hormone that is released from the hypothalmus where it stimulates the pituitary gland to secrete follicle-stimulating hormone and luteinizing hormone.

Gout A group of disorders of purine metabolism due to primary (inherited) or secondary causes such as chronic kidney disease.

G-protein–coupled receptors (GPCR) A large superfamily of membrane receptors whose intracellular effects are mediated by G proteins.

G-proteins Guanine nucleotide-binding proteins (G-proteins) are a family of proteins involved in transmitting chemical signals outside the cell, and causing changes inside the cell. T ey communicate signals from many hormones, neurotransmitters, and other signaling factors.

Graves disease A disorder of the thyroid of autoimmune etiology that causes hyperthyroidism. Characterized by having at least two of the following conditions: hyperthyroidism, goiter, and exophthalmos. Also known in Europe as Basedow disease.

Growth hormone (GH) A polypeptide of 191 amino acids that is produced by the anterior pituitary and affects the metabolism of carbohydrates, lipids, and proteins; it increases IGF-I.

Growth hormone–releasing hormone (GHRH) A hypothalamic hormone that regulates the release of growth hormone.

Gucagonoma A type of islet cell tumor of the alpha cells of the pancreas that secretes glucagon; some are malignant.

Gucose tolerance factor A biologically active complex of chromium and nicotinic acid that facilitates the reaction of insulin with receptor sites on tissues.

Guthrie test A semiquantitative microbiological assay for the determination of amino acids in blood or urine.

Gynecomastia Excessive development of the male mammary glands.

Half-life In endocrinology, the time required for a hormone to fall to half its original concentration in the specified fluid or blood.

Haplotype A combination of alleles (for different genes) that are located closely together on the same chromosome and that tend to be inherited together.

Hapten A chemically defined determinant that, when conjugated to an immunogenic carrier, stimulates the synthesis of antibody specific for the hapten.

Hartnup disease An inborn error of metabolism characterized by a massive aminoaciduria involving a group of neutral monoaminomonocarboxylic amino acids sharing a common renal reabsorption mechanism.

Hashimoto thyroiditis An autoimmune disorder in which the thyroid gland is attacked by a cell-mediated autoimmune process. Also known as Hashimoto disease and chronic lymphocytic thyroiditis, it is marked by (1) goiter, (2) chronic inflammation of the thyroid (thyroiditis), and (3) often hypothyroidism.

Hashitoxicosis Hyperthyroidism in patients with Hashimoto disease.

hCG stimulation test A test administered to assess the ability of the testes to respond to hCG and produce testosterone.

Helicobacter pylori A bacterium found in the mucous layer of the stomach. All strains secrete (1) proteins that cause inflammation of the mucosa and (2) the enzyme urease that produces ammonia from urea; some strains produce toxins that injure the gastric cells.

HELLP syndrome A life-threatening pregnancy complication usually considered to be a variant of preeclampsia and usually occurring between the 23rd and 39th weeks. T e name is an acronym for the diagnostic features: H – Hemolysis; EL – Elevated Liver enzymes; LP – Low Platelets.

Hematuria Blood in the urine.

Heme Any quadridentate chelate of iron with the four pyrrole groups of a porphyrin, further distinguished as ferroheme or ferriheme, referring to the chelates of Fe(II) and Fe(III), respectively.

Hemin A porphyrin chelate of $Fe3^{+}$ derived from red blood cells.

Hemochromatosis A rare genetic disorder caused by deposition of hemosiderin in the parenchymal cells, resulting in tissue damage and dysfunction of the liver, pancreas, heart, and pituitary. Also called iron overload disease.

Hemodiafiltration A type of hemofiltration with a dialytic component added. With it, blood flow is accelerated to twice that of conventional dialysis.

Hemoglobin T e oxygen-carrying pigment of the erythrocytes, formed by the developing erythrocyte in bone marrow. It is a conjugated protein containing four heme groups and globin, with the property of reversible oxygenation.

Hemoglobinopathy Any inherited disorder caused by abnormalities of hemoglobin, resulting in conditions such as sickle cell anemia, hemolytic anemia, or thalassemia.

Hemolysis Disruption of the red cell membrane causing release of hemoglobin and other components of red blood cells.

Hemolytic disease of the newborn (HDN) A disease of the fetus and newborn caused by maternal antibody-mediated fetal erythrocyte destruction.

Hemosiderin An intracellular storage form of iron; the granules consist of an ill-defined complex of ferric hydroxides, polysaccharides, and proteins having an iron content of about 33% by weight.

Hemosiderosis A focal or general increase in tissue iron stores without associated tissue damage. Hepatic and pulmonary forms of hemosiderosis are characterized by abnormal quantities of hemosiderin in the liver and lungs, respectively.

Henderson-Hasselbalch equation An equation that defines the relationship among pH, bicarbonate, and the partial pressure of dissolved carbon dioxide gas.

Hepatic encephalopathy A condition caused by the deleterious effects of liver failure on the central nervous system. Features include confusion ranging to unresponsiveness (coma).

Hepatic failure A condition of severe liver dysfunction that is accompanied by a loss of normal liver functions.

Hepatitis Inflammation of the liver. Typically divided into acute (duration of weeks to months) and chronic (lasting for more than 6 months).

Hepatocellular carcinoma (HCC) A cancer arising from hepatocytes.

Hepatocyte An epithelial liver cell that performs most of the synthetic and metabolic functions of the liver.

Hepcidin A hormone produced by liver cells, in response to signals from a complex pathway, that decreases iron mobilization across intestinal and macrophage membranes, preventing excess iron in the blood.

Hereditary angioedema (HAE) Genetic disorder characterized by recurrent episodes of severe swelling.

Hereditary coproporphyria (HCP) An autosomal dominant hepatic porphyria caused by mutations of the CPOX gene (locus: 3q12) that result in partial deficiency of coproporphyrinogen oxidase activity.

Hereditary hemochromatosis A genetically heterogeneous group of inherited disorders of iron metabolism characterized by failure to prevent excessive amounts of iron from entering the circulatory pool and accumulating in the tissues.

Hereditary persistence of fetal hemoglobin A condition characterized by continued production of fetal hemoglobin beyond the point when it is normally replaced by hemoglobin A.

Heterochromatin Genomic regions that are gene poor or span transcriptionally silent genes and are more densely packed during interphase.

Heteroduplex A DNA duplex with internal mismatches or loops.

Hetero-duplex analysis (HDA) A type of mutation scanning in which a segment of DNA is screened by gel or capillary electrophoresis for mismatch pairing between normal and mutated base pairs.

Heterogeneous immunoassay An immunochemical reaction in which it is assumed that the formation of the antigen/antibody complex occurs more quickly than the breakdown of the complex into antigen and antibody; in this assay, the antigen is labeled and separation of the free from the bound labeled antigen is required.

Heteroplasmy T e presence of more than one population of mitochondrial DNA sequences in a cell consequent to the accumulation of sequence variations.

High-performance liquid chromatography (HPLC) Liquid chromatography that uses columns containing small particles of stationary phase and requiring high pressure to push the mobile phase past the stationary phase.

High-resolution melting analysis (HRMA) An indirect method of observing DNA dissociation by using dyes that fluoresce in the presence of double-stranded DNA but not single-stranded DNA.

Hirsutism Abnormal hairiness, especially an adult male pattern of hair distribution in females.

Histones A class of structural proteins involved in the three-dimensional organization of nuclear DNA.

Holoenzyme Active enzyme formed by combination of a coenzyme and an apoenzyme.

Homeostasis T e maintenance of equilibrium of internal body functions in response to external changes.

Homocystinuria A condition characterized by the excretion of excess homocystine in the urine; this biochemical abnormality has a variety of autosomal recessive genetic causes as well as nongenetic causes.

Homoduplex A perfectly matched DNA duplex.

Homogeneous immunoassay An immunochemical reaction in which the activity of the label attached to the antigen is modulated directly by antibody binding; this assay does not require a separation.

Homoplasmy T e presence of a homogeneous population of mitochondrial genomes in a cell.

Homovanillic acid (HVA) A product of dopamine metabolism; elevated urinary concentrations are used to diagnose neuroblastoma.

Hook effect A phenomenon occurring with certain immunoassays due to very high concentrations of a particular analyte; it results in a false negative result. T e hook effect mostly affects one-step immunometric assays.

Hormone A chemical substance that has a specific regulatory effect on the activity of a certain organ or organs on cell types.

Human antimouse antibodies (HAMA) Antibodies made by humans that bind mouse proteins. T eir presence in body fluids causes both positive and negative interferences in two-site mouse monoclonal antibody-based assays.

Human chorionic gonadotropin (hCG) A placental glycoprotein hormone that stimulates the ovary to produce progesterone.

Human Genome Project A project undertaken by the International Human Genome Sequencing Consortium to decipher the three billion base pairs in the human genome; the project was completed in 2003.

Human placental lactogen (hPL) A placental hormone, similar in structure and function to growth hormone, that disappears from the blood immediately after delivery.

Humoral hypercalcemia of malignancy (HHM) A malignancy caused by bone resorption mediated by circulating factors released from distant tumor cells.

Hybridization T e annealing or pairing of two DNA strands.

Hydramnios (or polyhydramnios) An abnormality of pregnancy characterized by an accumulation of excess amniotic fluid.

Hydrops fetalis A condition in which a fetus or newborn baby accumulates fluids, causing swollen arms and legs and impaired breathing.

5-Hydroxyindoleacetic acid (5-HIAA) A metabolite of serotonin (5-hydroxytryptamine) that is excreted in large amounts by patients with carcinoid tumors.

11β-Hydroxylase deficiency A type of congenital adrenal hyperplasia due to 11β-hydroxylase deficiency; it is one of a group of disorders (collectively called congenital adrenal hyperplasia) that affect the adrenal glands.

21-Hydroxylase deficiency A deficiency of this enzyme results in decreased cortisol synthesis and increased synthesis of male hormones by the adrenal; three types are described: (1) salt-wasting, (2) simple virilizing, and (3) nonclassical.

3β-Hydroxysteroid dehydrogenase deficiency An inherited disorder that affects hormone-producing glands, including the gonads (ovaries in females and testes in males) and the adrenal glands.

Hyperaldosteronism A condition in which the adrenal gland secretes and releases increased quantities of aldosterone.

Hyperandrogenism A condition characterized by excessive production and/or secretion of androgens.

Hyperbilirubinemia Excessive concentrations of bilirubin in the blood, which may lead to jaundice; the hyperbilirubinemias are classified as conjugated or unconjugated, according to the present form of bilirubin in the blood.

Hypercalcemia Increased concentration of calcium in plasma; manifestations include fatigability, muscle weakness, depression, anorexia, nausea, and constipation; most commonly caused by primary hyperparathyroidism or malignancy.

Hypercalcemia-associated malignancy (HAM) A malignancy characterized by hypercalcemia.

Hyperemesis gravidarum Extreme, excessive, and persistent vomiting in early pregnancy that may lead to dehydration and malnutrition.

Hyperglycemia Increased glucose concentrations in the blood.

Hypergonadotropic hypogonadism A condition characterized by (1) defective development of ovaries or testes, (2) excess pituitary gonadotropin secretion, and (3) delayed sexual development and growth delay.

Hyperkalemia A concentration of serum potassium above the reference interval limit of 5.0 mmol/L.

Hypermagnesemia A condition characterized by abnormally high concentrations of magnesium in blood plasma.

Hypernatremia A concentration of serum sodium above the reference interval limit of 150 mmol/L.

Hyperornithinemia-Hyperammonemia-Homocitrullinuria (HHH) syndrome An autosomal recessive syndrome characterized by increased plasma concentrations of ornithine, postprandial hyperammonemia and homocitrullinuria, and aversion to protein ingestion; the affected gene codes for the mitochondrial ornithine transporter, ornithine translocase.

Hyperphosphatemia A condition characterized by abnormally high concentrations of phosphates in blood plasma.

Hyperprolactinemia A condition characterized by increased levels of prolactin in the blood; in women it is associated with amenorrhea and galactorrhea, and in men it has been reported to cause hypogonadism, impotence, and in some cases gynecomastia.

Hypertension A medical condition characterized by high arterial blood pressure.

Hyperthyroidism A condition caused by excessive production of iodinated thyroid hormones. Symptoms and signs include increased basal metabolic rate, enlargement of the thyroid gland, rapid heart rate, high systolic blood pressure, and a number of secondary symptoms.

Hypertrichosis Excessive growth of hair.

Hyperuricemia An excess of uric acid or urates in the blood with many causes; it is a prerequisite for the development of gout and may lead to renal disease.

Hypervitaminosis An unhealthy condition resulting from excessive amounts of a vitamin.

Hypervolemia Abnormal increase in the volume of circulating fluid (plasma) in the body.

Hypocalcemia A condition characterized by a low concentration of calcium in plasma.

Hypoglycemia Decreased glucose concentrations in the blood.

Hypogonadotropic hypogonadism A condition with impaired production of the hormones (LH and FSH) that stimulate the gonads; lack of LH and FSH leads to decreased sex hormone production by the gonads and accompanying symptoms.

Hypokalemia A concentration of serum potassium below the reference interval limit of 3.5 mmol/L.

Hypomagnesemia A condition characterized by a low concentration of magnesium in blood.

Hyponatremia A concentration of serum sodium below the reference interval limit of 136 mmol/L.

Hypoparathyroidism T e condition produced by greatly reduced function of the parathyroid glands.

Hypophosphatemia A condition characterized by a low concentration of phosphate in blood.

Hypothyroidism A condition of deficient thyroid gland activity leading to lethargy, muscle weakness, and intolerance to cold.

Hypouricemia Decreased uric acid concentration in the blood, secondary to a number of underlying conditions such as severe hepatocellular disease and defective renal tubular reabsorption.

Hypovitaminosis An unhealthy condition resulting from too little of a vitamin; interchangeable with avitaminosis.

Hypovolemia A condition characterized by an abnormal decrease in the volume of circulating blood in the body.

Icterus A condition characterized by hyperbilirubinemia and deposition of bile pigments in the skin, mucous membranes, and sclera, with resulting yellow appearance of the patient; called also jaundice.

ICTP An antigen produced when type I collagen is digested by matrix metalloproteinases, yielding cross-linked carboxy-terminal telopeptide of type I collagen; a serum marker for bone resorption.

Idiopathic postprandial syndrome Repeated occurrence of the clinical manifestations of hypoglycemia after meals.

IgA nephropathy A common, chronic form of glomerulonephritis marked by hematuria and proteinuria and by deposits of immunoglobulin A in the mesangial areas of the renal glomeruli.

Immunoassay An assay based on the reaction of an antigen with an antibody specific for the antigen.

Immunogen A substance capable of inducing an immune response.

Immunoglobulin superfamily (IgSF) A large group of cell surface and soluble proteins that are involved in the recognition, binding, or adhesion processes of cells.

Immunoglobulins A family of proteins also known as antibodies that contain highly specific antigen-binding sites consisting of two identical heavy (H) chains encoded on chromosome 14 and two identical light (L) chains encoded on chromosome 2.

Immunostrip (immunosensor) A point-of-care device in which the recognition element is an antibody that binds to the analyte; the binding event is typically detected by an optical mechanism.

Immunosuppression T e prevention or diminution of the immune response by irradiation or by administration of antimetabolites, antilymphocyte serum, or specific antibody.

Impaired glucose tolerance (IGT) A term denoting values of fasting plasma glucose or results of an oral glucose tolerance test that are abnormal but not high enough to be diagnostic of diabetes mellitus.

In vitro fertilization (IVF) A procedure in which (1) eggs (ova) from a woman's ovary are removed, (2) the removed eggs are fertilized with sperm in a laboratory procedure, and (3) the fertilized egg (embryo) is returned to the woman's uterus.

Inborn error of metabolism (IEM) Inherited disorder in which a specific enzyme defect causes a metabolic block in the individual at birth or in later life.

Incretin Any of various gastrointestinal hormones and factors that act as potent stimulators of insulin secretion, such as gastric inhibitory polypeptide.

Indel A sequence variant arising from both an insertion and a deletion.

Index test In diagnostic accuracy studies, the "new" test or the test of interest.

Indirect bilirubin Free bilirubin that has not been conjugated with glucuronic acid.

Infertility T e inability to conceive after one year of unprotected intercourse.

Informatics In a clinical sense, the design, management, and study of systems that store and communicate medical information; in the clinical laboratory, this refers to the communication and management of information related to laboratory testing and test interpretation.

Inhibin A peptide hormone secreted by the follicular cells of the ovary and the Sertoli cells of the testis that inhibits secretion of follicle stimulating hormone (FSH) from the anterior pituitary.

Inhibin A Ovary-produced inhibin A is an important negative feedback hormone that suppresses pituitary secretion of FSH during the late follicular and luteal phases of the menstrual cycle.

Inhibitor A substance that reduces the rate of an enzymatic reaction and is classified as reversible or irreversible.

Insertion An extra DNA sequence that is present in one sample compared with a reference sequence.

Insulin A protein hormone produced by β-cells of the pancreas that decreases blood glucose concentrations.

Insulin resistance Impairment of normal biologic responses to insulin.

Insulinlike growth factors (IGF) Serum peptides with insulin-like actions, formerly called somatomedins.

Intergenic DNA sequence between genes.

International normalized ratio (INR) A method of reporting prothrombin time results for patients receiving oral anticoagulant therapy

International System of Units (SI) A system of units for analytical results that is based on the cubic meter as the reference volume and is an internationally (except in the United States) adopted system of measurement. T e units of the system are called SI units.

International unit T e quantity of enzyme that catalyzes one micromole of substrate per minute.

Interphase T e period between cell divisions.

Interstitial nephritis Primary or secondary disease of the renal interstitial tissue.

Intoxication A state of impaired mental or physical functioning resulting from ingestion of alcohol or drug.

Intracellular fluid (ICF) T e portion of the total body water (TBW) with its dissolved solutes that is within the cell membranes.

Intron A noncoding region of a gene, located between exons, that will not be translated into protein. It is spliced out during messenger RNA (mRNA) processing.

Ion An atom that has acquired an electrical charge by losing or gaining one or more electrons.

Ion trap A component of a trapping-type mass spectrometer where ions are held in a spatially confined region of space using, for example, a magnetic or electrostatic field; manipulation of the traps allows m/z measurements to be performed.

Ion-exchange chromatography A separation mechanism that is based on the exchange of ions between a charged stationary phase and oppositely charged ions in the mobile phase.

Ionization The production of an ion from a neutral atom or molecule using various techniques including but not limited to chemical ionization or electrospray ionization; ionization is required for all mass spectrometry techniques.

Ion-selective electrode An electrode that selectively interacts with a single ionic species; the potential produced at the membrane/sample solution interface is proportional to the logarithm of the ionic activity or the concentration of the ion in question.

Irinotecan A DNA topoisomerase inhibitor used as an antineoplastic drug in the treatment of colorectal carcinoma.

ISO 9000 A set of four standards used to ensure quality management and quality assessment developed by the International Organization for Standardization.

Isoelectric focusing An electrophoretic technique that separates amphoteric compounds within a medium that possesses a stable pH gradient.

Isoelectric point (pI) The pH at which a molecule has no net charge and will not migrate during electrophoresis.

Isoenzyme A molecular form of an enzyme that originates at the level of the genes that encode the structures of the enzyme proteins in question.

Isoform A form of an enzyme that is modified by post-translational processing.

Isotope A variant of a chemical element; each variant differs in the number of neutrons in the nucleus and therefore in atomic weight from other isotopes of the same element.

Isotope dilution mass spectrometry (IDMS) An analytical technique used to quantify a compound relative to an isotopic species of known or fixed concentration using isotopically labeled internal standards.

Isovaleric acidemia A metabolic disorder which disrupts or prevents normal metabolism of the branched-chain amino acid leucine. It is characterized by acidosis, coma, and an unpleasant body odor.

Jaffe reaction The reaction of creatinine with alkaline picrate to form a colored compound.

Jaundice A clinical finding characterized by hyperbilirubinemia and deposition of pigment in the skin, mucous membranes, and sclera with resulting yellow appearance; also called icterus.

Juxtaglomerular apparatus (JGA) A complex in the kidney whose function is the autoregulation of the glomerular filtration rate.

Kallmann syndrome A type of hypogonadotropic hypogonadism caused by failure of fetal gonadotropin-releasing hormone neurons to migrate to the hypothalamus.

Kashin–Bek disease (KBD) A chronic, endemic osteochondropathy (disease of the bone).

Katal The quantity of an enzyme that catalyzes a reaction rate of one mole of substrate per second.

Kernicterus A clinical syndrome of the neonate resulting from high concentrations of unconjugated bilirubin that passes the immature blood-brain barrier of the newborn and causes degeneration of cells of the basal ganglia and hippocampus.

Keshan disease A fatal, congestive cardiomyopathy caused by deficiency of essential trace elements in the diet.

Ketoacidosis A condition characterized as acidosis accompanied by the accumulation of ketone bodies (ketosis) in the body tissues and fluids.

Ketone An organic compound that has a carbonyl group (carbon atom double-bonded to an oxygen atom) at any position other than at the end of the carbon chain.

Klinefelter syndrome A condition in a male characterized by (1) two X and one Y chromosomes, (2) infertility, (3) small testicles, (4) sparse facial and body hair, and (5) enlarged breasts.

Kwashiorkor A form of protein-energy malnutrition produced by severe protein deficiency.

Label Any substance with a measurable property attached to an antigen, antibody, or binding substance.

Laboratory medicine A component of laboratory science that is involved in the selection, provision, and interpretation of diagnostic testing of individual specimens.

Laboratory testing A process conducted in a clinical laboratory to rule in or rule out a diagnosis, to select and monitor disease treatment, to provide a prognosis, to screen for a disease, or to determine the severity of and monitor a physiological disturbance.

Lactate An intermediary product in glucose metabolism that accumulates in the blood predominantly when tissue oxygenation is decreased, as during strenuous exercise; an increased blood lactate concentration is called lactic acidosis.

Lactate dehydrogenase An oxidoreductase enzyme that reversibly catalyzes the reduction of pyruvate to l-lactate, using NADH (reduced form of nicotinamide adenine dinucleotide) as an electron donor.

Lactose intolerance A condition due to lactase deficiency leading to malabsorption of lactose and causing symptoms of flatulence, abdominal discomfort, bloating, or diarrhea after ingesting milk or foods containing lactose.

Lamellar bodies Packages of phospholipids that are produced by type II alveolar cells and represent the storage form of surfactant. They are similar in size to platelets and are present in amniotic fluid.

Lamellar body count (LBC) Number of lamellar bodies in amniotic fluid. LBC increases as gestation advances. Most electronic cell counters will count the lamellar bodies.

Lanugo A very fine, soft, and usually unpigmented downy hair on the body of a fetus or newborn baby.

Laron syndrome An autosomal recessive syndrome of skeletal growth retardation due to impaired ability to synthesize insulin-like growth factor I, usually because of growth hormone receptor defects. Also called Laron dwarfism.

Late-onset 21-hydroxylase deficiency (NCAH) A condition due to 21-hydroxylase deficiency. It is a common, milder form of congenital adrenal hyperplasia (CAH) characterized by a later onset of androgen excess symptoms seen in females and precocious pseudopuberty in both sexes. Also known as nonclassical congenital adrenal hypoplasia.

L-Dopa An amino acid—3,4-dihydroxyphenylalanine—produced by oxidation of tyrosine by tyrosine hydroxylase; the precursor of dopamine and an intermediate product in the biosynthesis of norepinephrine, epinephrine. Can also be formed in melanocytes by the actions of tyrosinase as part of the production of melanin.

Lean production A quality process that is focused on creating greater value by eliminating activities that are considered waste.

Leber's hereditary optic neuropathy (LHON) A neuropathy transmitted from mother to children that is characterized by a degeneration of retinal ganglion cells (RGCs) and their axons that leads to a loss of central vision.

Levey-Jennings control chart A graphical display with observed control values plotted against an acceptable range of values, indicated on the chart by lines for upper and lower control limits, commonly indicated as the mean control value plus or minus three standard deviations.

Leydig cell A type of cell in the testes that secretes testosterone.

LH surge A sharp increase in serum concentrations of luteinizing hormone seen near the middle of the menstrual cycle about one to two days before ovulation.

Liddle syndrome A rare autosomal dominant syndrome resulting from epithelial sodium channel mutations that lead to abnormally increased channel function.

Ligandin An hepatic transport protein; measurement of it in serum and urine may be a means of estimating the severity of hepatocellular necrosis.

Ligase An enzyme that covalently joins two DNA strands.

Ligase chain reaction (LCR) A DNA amplification technique that uses four primers instead of two and uses the ligase to ligate or join two segments of DNA.

Light Energy transmitted via electromagnetic waves that are characterized by frequency and wavelength; light is composed of photons whose energy is inversely proportional to the wavelength.

Light scattering A physical phenomenon that results from the interaction of light with particles in solution.

Likelihood ratio T e probability of occurrence of a specific test value given that the disease is present divided by the probability of the same test value if the disease was absent.

Limit of detection An assay characteristic defined as the lowest value that significantly exceeds the measurements of a blank sample.

Lineweaver-Burk plot A plot of the reciprocal of the velocity of an enzyme catalyzed reaction (ordinate; y-axis) against the reciprocal of the substrate concentration (abscissa; x-axis).

Linkage disequilibrium Nonrandom association of alleles at different loci; the rate reflects rates of recombination and is used as a measure of distance between the loci. See also centiMorgan.

Lipase A hydrolase that hydrolyzes glycerol esters of long-chain fatty acid.

Lipids A class of compounds that are soluble in organic solvents but are nearly insoluble in water and that contain nonpolar carbon-hydrogen bonds.

Lipoprotein(a) A lipoprotein structurally similar to low-density lipoprotein but containing a carbohydrate-rich protein and that carries only a relatively small fraction of total cholesterol; it is considered particularly pro-atherogenic.

Lipoprotein-associated phospholipase A2 An enzyme member of the phospholipase A2 superfamily that cleaves oxidized phosphatidylcholine components of lipoprotein particles.

Lipoproteins Spherical particles involved in the transport of lipids with nonpolar neutral lipids (triglycerides and cholesterol esters) in their core and more polar amphipathic lipids (phospholipids and free cholesterol) at their surface.

Liquid chromatography (LC) Column chromatography using a liquid mobile phase.

Liquid chromatography–mass spectrometry (LC-MS) An analytical process that uses a liquid chromatograph coupled to a mass spectrometer.

Lithotripsy T e crushing of a calculus within the urinary system or gallbladder, followed at once by the washing out of the fragments; it is done either surgically or by several different noninvasive methods.

Long-chain 3-hydroxyacyl-CoA dehydrogenase (LCHAD) deficiency A metabolic disease characterized by defective fatty acid oxidation due to a defect in an enzyme in the β-oxidation pathway.

Loop of Henle T e U-shaped part of the renal tubule, extending through the medulla from the end of the proximal convoluted tubule to the beginning of the distal convoluted tubule.

Loop-mediated amplification (LAMP) A single tube technique for the amplification of DNA that uses a single-temperature incubation.

Lucey-Driscoll syndrome A potentially fatal disorder characterized by severe hyperbilirubinemia present at birth, which accumulates in the brain.

Luteinizing hormone (LH) A hormone produced by the anterior lobe of the pituitary gland that stimulates ovulation and the development of the corpus luteum in the female and the production of testosterone by the interstitial cells of the testis in the male.

Lymphoma Any neoplastic disorder of the lymphoid tissue.

Lysergic acid diethylamide (LSD) A derivative of an alkaloid found in certain fungi that has hallucinogenic properties.

Malabsorption An abnormality in the absorption of nutrients.

MALDI Acronym for matrix-assisted laser desorption/ionization. It is a soft ionization technique that allows the analysis of biomolecules and large organic molecules which tend to be fragile and fragment when ionized by more conventional ionization methods.

Maldigestion An abnormality of the digestive process due to dysfunction of the pancreas or small intestine.

Maple syrup urine disease (MSUD) An autosomal recessive metabolic disorder affecting branched-chain amino acids (leucine, isoleucine, and valine). T e urine of affected individuals smells like maple syrup.

Marasmus A form of protein-energy malnutrition predominantly due to prolonged severe caloric deficit.

Marfan syndrome A congenital disorder of connective tissue characterized by long limbs and caused by abnormal fibrillin metabolism; it affects various structures, notably heart valves and aorta.

Marijuana A crude preparation of the leaves and flowering tops of Cannabis sativa plants, usually used in cigarettes and inhaled as smoke for its euphoric properties.

Mass analysis T e process by which a mixture of ionic species is identified according to the mass-to-charge (m/z) ratios (ions).

Mass spectrometer An analytical instrument that first ionizes a target molecule and then separates and measures the mass-to-charge (m/z) ratio of these molecules or their fragments; this instrument interfaces with other instruments including but not limited to a second mass spectrometer or a gas chromatograph.

Mass spectrometry Study of matter through the formation of gas-phase ions that are characterized by their mass, charge, structure, and/or physico-chemical properties.

Mass spectrum A plot of the relative abundance of each ion plotted as a function of its mass-to-charge (m/z) ratio.

Mass-to-charge ratio (m/z>) T e quantity formed by dividing the mass of an ion by its charge.

Material Safety Data Sheet (MSDS) A technical bulletin that contains information about a hazardous chemical, such as chemical composition, chemical and physical hazard, and precautions for safe handling and use.

Matrix In relation to analytical methods, human serum that contains analytes.

MDA (3,4-methylenedioxyamphetamine) A psychedelic drug of the phenethylamine and amphetamine classes of drugs.

MDMA (3,4-methylenedioxy-N-methylamphetamine) A drug of the phenethylamine and amphetamine classes of drugs. Known as "ecstasy."

Measurand See Analyte.

Measuring interval T e analyte concentration range over which measurements are within the declared tolerances for imprecision and bias; also referred to as "reportable range."

Mechanism of action T e mechanism by which a pharmacologically active substance produces an effect on a living organism or in a biochemical system.

Meconium A dark green fecal material that accumulates in the fetal intestines and is discharged at or near the time of birth.

Medium-chain acyl-CoA dehydrogenase (MCAD) deficiency A disorder of fatty acid oxidation that impairs the body's ability to break down medium-chain fatty acids into acetyl-CoA.

Medullary thyroid cancer (MTC) A slow-growing tumor associated with multiple endocrine neoplasia (MEN) syndromes.

Mees' lines Lines of discoloration across the nails of the fingers and toes.

Megaloblastic anemia Any anemia characterized by megaloblasts in the bone marrow, such as pernicious anemia.

Melatonin A hormone synthesized by the pineal gland in many species of animals; its secretion increases during exposure to light.

Melting curve analysis A direct measurement of double-stranded DNA (dsDNA) dissociation during heating. As the temperature is raised, the double strand dissociates resulting in an increase in the absorbance of the solution containing the DNA.

Melting temperature (Tm) T e temperature at which 50% of the DNA strands are in the random coil or single-stranded (ssDNA) state. It depends on the length of the DNA molecule and its specific nucleotide sequence.

Menarche T e establishment or beginning of the menstrual function.

Menkes disease An X-linked recessive disorder of copper metabolism caused by mutations in the ATP7A gene (locus: Xq12- q13), which encodes a copper transporter.

Menopause Cessation of menstruation, which usually occurs around the age of 50.

Menses T e monthly flow of blood from the genital tract of women.

Mesothelioma A tumor derived from mesothelial tissue (peritoneum, pleura, pericardium); both benign and malignant varieties exist. Malignant varieties are often the result of excessive exposure to asbestos.

Metabolic acidosis Any of the various kinds of acidosis in which the acid-base status of the body shifts toward the acid side because of loss of base or retention of acids other than carbonic acid.

Metabolic alkalosis A pathological process that leads to the accumulation of base that raises the bicarbonate concentration and increases the pH; also known as primary bicarbonate excess.

Metabolizer classification A classification of four drug-metabolism phenotypes as they relate to an individual's metabolic efficiency for processing a specific therapeutic drug. The four types are (1) poor metabolizers (PMs), (2) ultra-rapid metabolizers (UMs), (3) extensive metabolizers (EMs), and (4) intermediate metabolizers (IMs).

Metanephrine A catecholamine metabolite resulting from O-methylation of epinephrine; formed mainly within adrenal chromaf n cells; excreted mainly in the urine as a sulfate-conjugated metabolite; measurements of the free and conjugated metabolites provide useful tests for diagnosis of pheochromocytoma.

Metastasis The spread of cancer from one part of the body to another.

Methadone A synthetic opioid analgesic, possessing pharmacologic actions similar to those of morphine and heroin and similar potential for addiction; used as an analgesic and as a narcotic abstinence syndrome suppressant in the treatment of heroin addiction.

Methamphetamine (Ritalin) A sympathomimetic amine closely related chemically to both amphetamine and ephedrine, having actions similar to those of amphetamine.

Methemoglobin A form of hemoglobin where its iron atom is changed from the ferrous to the ferric state.

Method comparison Comparison of measurements by two methods that is carried out objectively using statistical procedures and graphics displays.

Methoxyhydroxyphenylglycol (MHPG) A metabolite of epinephrine and norepinephrine formed primarily from O-methylation of dihydroxyphenylglycol and in smaller amounts from deamination of normetanephrine and metanephrine; found in brain, blood, CSF, and urine, where its concentration is used to measure catecholamine turnover.

Methylmalonic acidemia An autosomal recessive metabolic disorder resulting from defects in the metabolic pathway in which methylmalonyl-coenzyme A (CoA) is converted into succinyl-CoA by the enzyme methylmalonyl-CoA mutase.

Methylphenidate A central stimulant used in the treatment of attention-deficit/hyperactivity disorder, narcolepsy, and certain forms of depression

Metric system A system of weights and measures based on the meter as a standard unit of length, the liter as a standard unit of volume, and the gram as a standard unit of mass.

Michaelis-Menten constant (Km) A constant for a given enzyme acting under given conditions; the experimentally determined substrate concentration at which the enzymatic reaction velocity equals ½ of the maximum velocity of the enzymatic reaction.

Microarray-based genotyping A molecular technique used to simultaneously screen hundreds to thousands of genetic markers per individual.

Microcephaly A condition characterized by an abnormally small head circumference; associated with a small brain (microencephaly).

Microchip electrophoresis An electrophoretic technique whereby separation is conducted in fluidic channels on a microchip and detection occurs through laser-induced fluorescence.

MicroRNA (miRNA) Short noncoding RNA (ncRNA) molecules around 22 nucleotides in length that play a role in regulation of gene expression by interfering with effective translation of mRNA to proteins.

Microsatellites Short segments of DNA (1 to 13 bases long) that are repeated end to end. Also known as short tandem repeats (STRs).

Microtiter plate A flat plate containing a two-dimensional array of multiple "wells" used as small reaction chambers. Such plates typically have 6, 24, 96, 384, or even 1536 sample wells arranged in a rectangular array.

Minamata disease A condition characterized by symptoms of alkyl mercury poisoning that were seen between 1953 and 1958 among individuals who ate seafood from a bay in Japan that was polluted with alkyl mercury compound.

Mineralization The process by which the body uses minerals to build bone structure.

Mineralocorticoids Any of the group of 21-carbon corticosteroids (principally aldosterone) that contribute to the regulation of (1) water, (2) acid-base, and (3) electrolyte balance in the body.

Minisatellites Repeated segments of DNA that are 14 to 500 bases long. Also known as sequences with a variable number of tandem repeats (VNTRs).

Miosis Constriction of the pupil of the eye, resulting from a normal response to an increase in light or caused by certain drugs or pathological conditions.

Missense A nucleotide substitution that changes a codon to the code for a different amino acid. Although these sequence changes are commonly referred to as missense "mutations," this is strictly a misnomer, because they may be benign and cause no disease.

Mitochondrial DNA The circular DNA within a mitochondrial organelle that codes for polypeptides involved in the oxidative phosphorylation pathway; this DNA is typically transmitted across generations by maternal inheritance.

Mixed acid-base disturbance The occurrence of more than one acid-base disorder simultaneously; the blood pH may be low, high, or within the reference interval.

Mnemonics A mnemonic or mnemonic device is any learning technique that aids information retention.

Mobile phase A gas or a liquid that flows in a chromatographic system and carries the sample past the stationary phase.

Model for End-Stage Liver Disease (MELD) Score A scoring system for assessing the severity of chronic liver disease.

Molar absorptivity (ε) A proportionality constant for a compound that is the measure of the absorption of radiant energy at a given wavelength as it passes through a solution of that compound at a concentration of 1 mol/L; expressed mathematically as absorbance divided by the product of the concentration of a substance in mol/L and the sample path length in centimeters ($\varepsilon = A/bc$).

Molar pregnancy A type of pregnancy caused by abnormal proliferation of placental tissue in the uterus. Also known as a hydatidiform mole.

Molecular diagnostics Use of molecular biology techniques for the purposes of prevention, diagnosis, and follow-up or prognosis of disease; and selection, optimization, and monitoring of therapies.

Monoclonal gammopathy of undetermined significance (MGUS) A condition in which a paraprotein is found in an individual's blood.

Morula A solid ball of cells resulting from division of a fertilized ovum and from which a blastula is formed.

Mucin A high-molecular-weight glycoprotein complex.

Müllerian duct Either of two embryonic tubes extending along the mesonephros that become the uterine tubes, uterus, and part of the vagina in the female and that form the prostatic utricle in the male.

Müllerian duct agenesis A congenital malformation characterized by a failure of the Müllerian duct to develop, with resultant absence or malformation of the vagina and/or uterus.

Multiple endocrine neoplasia (MEN) A group of genetic disorders characterized by hyperplasia and hyperfunction of two or more components of the endocrine system such as the parathyroid and other hormonal glands.

Multiple myeloma A cancer in which antibody-producing plasma cells grow in an uncontrolled and malignant manner.

Multiple of the median (MoM) In clinical screening, the statistic used to normalize analyte values.

Multiple-channel analysis Type of analysis in which each specimen is subjected to multiple analytical processes so that a set of test results is obtained on a single specimen; similar to random-access analysis.

Multiplex analysis Simultaneous assessment of multiple analytes in a single sample.

Multiplex ligation-dependent probe amplification (MLPA) A variation of PCR that permits multiple targets to be amplified with only a single primer pair.

Mutation A disease-causing sequence variation.

Myeloperoxidase An enzyme that catalyzes the conversion of chloride anion and hydrogen peroxide to hypochlorite, a metal chlorinating oxidant with a potent microbicidal activity.

Myocardial ischemia Deficiency of blood supply to the heart muscle due to obstruction or constriction of the coronary arteries.

Myocardium The middle and thickest layer of the heart wall, composed of cardiac muscle.

Myoglobin A heme-containing protein found in red skeletal muscle.

Myxedema A severe form of hypothyroidism in which there is accumulation of mucopolysaccharides in the skin and other tissue, leading to a thickening of facial features and a doughy induration of the skin.

N-acetyltransferase (NAT) A family of metabolic enzymes that acetylate drugs.

National Institutes of Health (NIH) Pharmacogenomics Research Network (PGRN) A network of scientists focused on understanding how a person's genes affect his or her response to medicines.

Necrosis The sum of the morphological changes indicative of cell death and caused by the progressive degradative action of enzymes; it may affect groups of cells or part of a structure or an organ.

Nephelometry The detection and measurement of light energy scattered or reflected toward a detector that is not in the direct path of the transmitted light.

Nephritis Inflammation of the kidney with focal or diffuse proliferation or destructive processes that may involve the glomerulus, tubule, or interstitial renal tissue.

Nephrolithiasis A condition marked by the presence of renal calculi (stones).

Nephron The anatomical and functional unit of the kidney, consisting of the (1) renal corpuscle, (2) proximal convoluted tubule, (3) descending and ascending limbs of loop of Henle, (4) distal convoluted tubule, and (5) collecting tubule.

Nephrotic syndrome General name for a group of diseases involving defective kidney glomeruli, characterized by massive proteinuria and lipiduria with varying degrees of edema, hypoalbuminemia, and hyperlipidemia.

Nernst equation The equation used to determine the reduction potential for a given redox couple and used to correlate chemical energy with the electrical potential of an electrochemical cell.

Neural tube defect (NTD) A major birth defect resulting from the abnormal development of the neural tube present during embryonic life that gives rise to the central nervous system; the two most common NTDs are spina bifida and anencephaly.

Neuroblastoma A sarcoma consisting of malignant neuroblasts, usually arising in the autonomic nervous system (sympathicoblastoma) or in the adrenal medulla; considered a type of neuroepithelial tumor that affects mostly infants and children up to 10 years of age.

Neuroendocrine tumors (NET) Neoplasms that arise from cells of the endocrine and peripheral nervous systems, most commonly in the digestive tract, but also found in the lung, pancreas, pituitary, thyroid, and other tissues.

Neurofibromatosis 1 (NF1) An autosomal dominant disorder due to mutation in the NF1 gene.

Neurohypophysis The posterior lobe of the pituitary gland, making up the neural portion that secretes various hormones.

NIOSH U.S. National Institute for Occupational Safety and Health.

Non-alcoholic fatty liver disease (NAFLD) A condition characterized by the buildup of extra fat in liver cells that is not caused by alcohol.

Non-alcoholic steatohepatitis (NASH) An inflammatory disease of the liver of uncertain pathogenesis.

Noncompetitive immunoassay An immunoassay in which a capture antibody is bound to a surface with subsequent antigen binding followed by the addition of a second labeled antibody that reacts with the initial antigen/antibody complex.

Nonketotic hyperglycinemia (NKHG) A usually fatal autosomal-recessive aminoacidopathy with accumulation of glycine in body fluids, particularly the blood, urine, and cerebrospinal fluid.

Nonparametric analysis A statistical approach to reference value analysis that requires no assumptions about the nature of the distribution; thus, it can be applied to distributions that are Gaussian or non-Gaussian.

Nonsense A nucleotide substitution that results in a stop codon, prematurely terminating the protein.

Non-ST segment elevation myocardial infarction (NSTEMI) A myocardial infarction in which the ST segment is not elevated in one lead or several leads of the EKG.

Norepinephrine (noradrenaline) A major neurotransmitter produced by some brain neurons and peripheral sympathetic nerves that acts on α- and β_1-adrenergic receptors; produced in the adrenal chromaf n cells as a precursor for epinephrine.

Normetanephrine An O-methylated metabolite of norepinephrine produced in extraneuronal cells and the adrenal medulla.

Northern blot A technique for identifying specific sequences of RNA in which RNA molecules are sequentially (1) separated by electrophoresis, (2) transferred to nitrocellulose, and (3) identified with a suitable probe.

N-telopeptide (NTx) A biochemical marker of bone resorption.

Nuchal translucency (NT) test A measurement of the size of the translucent space behind the neck of the fetus; made using ultrasound between 10 and 14 weeks of pregnancy. NT tends to be increased in chromosome disorders, such as Turner syndrome and Down syndrome.

Nuclease An enzyme that degrades nucleic acid.

Nucleic acid A polymer made of nucleotide monomers (a sugar moiety, a phosphoric acid, and purine or pyrimidine bases); examples are deoxyribonucleic acid (DNA) and ribonucleic acid (RNA).

Nucleic acid analogs Compounds that are analogous (structurally similar) to naturally occurring RNA and DNA. T ey are used in medicine and in molecular biology research.

Nucleosome A unit of chromatin consisting of nucleosome core particles (146 base pairs of double-stranded DNA [ds-DNA]) wound around a core of eight histone proteins; technically, a nucleosome also includes a linker DNA between nucleosomes, but the word often is used to mean the core particle.

5′-Nucleotidase A phosphatase that acts only on nucleoside-5′-phosphates, such as adenosine-5′-phosphate (AMP), releasing inorganic phosphate.

Nucleotide A unit of DNA or RNA, consisting of one chemical base (purine or pyrimidine) plus a sugar molecule (deoxyribose or ribose) and at least one phosphate group.

Nutriture T e status of the body in relation to nutrition, generally or with regard to a specific nutrient such as a trace element.

Obstructive uropathy Uropathy resulting from an obstruction in the tract.

Ochronosis A condition characterized by an accumulation of dark pigment in cartilage and other connective tissue that indicates alkaptonuria or phenol poisoning.

Odds ratio T e probability of the presence of a specific disease divided by the probability of its absence.

Okazaki fragment A relatively short fragment of DNA (with no RNA primer at the 5′ terminus) created on the lagging strand of DNA during DNA synthesis.

Oligohydramnios A condition in pregnancy characterized by a deficiency of amniotic fluid.

Oligomenorrhea Menses occurring at intervals longer than 35 days.

Oligonucleotide A short single-stranded polymer of nucleic acid.

Oligonucleotide ligation assay (OLA) A technique for determining the presence or absence of a specific nucleotide pair within a target gene, often indicating whether the gene is wild type (normal) or mutant (defective).

Oliguria Diminished urine production and excretion.

Omphalocele A birth defect in which the infant's intestine or other abdominal organs protrude from the navel.

Oncofetal antigen Protein produced during fetal life that decreases to low or undetectable levels after birth; reappears in some forms of cancer as the result of reactivation of genes in transformed malignant cells.

Oncogene A mutated normal cellular gene (proto-oncogene) that causes the malignant transformation of normal cells when activated.

Operator interface T e part of a device that the operator is required to use for the device to work (e.g., switch on a reader, entry of a patient or sample identification, calibration of the device).

Opiate/Opioid Opiate refers to any of a group of naturally occurring (poppy plant) or semi-synthetic narcotic alkaloids with pharmacological actions and chemical structure similar to morphine. Opioid is a general term that is applied to all substances with morphine-like properties, regardless of origin or chemical structure.

Optode An optical sensor that measures specific substances such as pH, blood gases, and electrolytes using dye immobilization, fluorescence quenching, or phosphorescence.

Oral glucose tolerance test (OGTT) T e most common kind of glucose tolerance test in which glucose is ingested by a fasting patient and their concentration of plasma glucose measured over time.

Ordinary least-squares regression (OLR) analysis A method used to estimate the unknown parameters in a linear regression assessment performed to minimize the sum of squared vertical distances between observed responses and responses predicted by linear approximation.

Organic acidemia A disorder of intermediary metabolism in which lack of an enzyme leads to buildup of an organic acid (from deamination of the amino acid) as opposed to the buildup of the parent amino acid.

Organification A process in the thyroid gland whereby iodide is oxidized and incorporated into tyrosyl residues (tyrosine) of thyroglobulin (Tg). Organification is catalyzed by the enzyme thyroperoxidase (TPO).

Ornithine translocase deficiency Ornithine translocase transports ornithine into the liver where it enters the urea cycle. When ornithine translocase is deficient, the concentrations of ornithine and ammonia increase in the blood.

OSHA Occupational Safety and Health Administration, formed by the federal government of the United States to formally regulate the oversight of employee safety.

Osmolal gap A difference between the observed and calculated osmolalities in serum analysis. T e calculated osmolar values include sodium concentration multiplied by 1.86, plus glucose and blood urea nitrogen, plus 9.

Osmometry Technique for measuring the concentration of dissolved solute particles in a solution.

Osmotic pressure The pressure required to stop osmosis through a semipermeable membrane between a solution and pure solvent.

Osteitis fibrosa A complication of hyperparathyroidism in which the bones are soft and often deformed; also called osteitis fibrosa cystica

Osteoblasts Cells responsible for formation of bone, including synthesis of type I collagen and noncollagenous proteins and mineralization of osteoid.

Osteocalcin (OC) A protein found in the extracellular matrix of bone and dentin and involved in regulating mineralization in the bones and teeth.

Osteoclasts Large, multinuclear cells responsible for resorption of bone.

Osteomalacia Inadequate or delayed mineralization of osteoid; the adult equivalent of rickets (interruption in the development and mineralization of the growth plate in children).

Osteopenia A condition characterized by decreased bone density occurs that is often predecessor to osteoporosis. It is diagnosed with a bone density test.

Osteoporosis A condition characterized by reduction in bone mass, leading to fractures with minimal trauma; postmenopausal osteoporosis occurs in women after menopause; senile osteoporosis occurs in both men and women later in life.

Ouchterlony technique A technique in which both antigen and antibody are allowed to diffuse to each other in a gel in a precipitation reaction.

Outcomes Results related to the quality or quantity of life of patients; examples include mortality, functional status, quality of life, and well-being.

Outcomes studies Studies performed to determine whether a medical intervention (such as a specific laboratory test) will improve patient outcomes.

Ovaries The paired female reproductive organs that produce ova (eggs), estrogens, and progesterone.

Ovulation The release of the ripe egg (ovum) from the ovary.

Oximetry A technique used to determine the oxygen saturation of arterial blood.

Oxygen dissociation curve The sigmoidal curve obtained when $S O_2$ of blood is plotted against $P O_2$.

Oxygen saturation The fraction (percentage) of functional hemoglobin that is saturated with oxygen.

Oxyhemoglobin An hemoglobin that contains bound O_2.

Oxytocin A nonapeptide hormone synthesized in the hypothalamus and stored in the posterior lobe of the pituitary.

P50 $P O_2$ for a given blood sample at which the hemoglobin of the blood is half saturated with O_2; P50 reflects the affinity of hemoglobin for O_2.

Paget disease A localized, not metabolic bone disease characterized by osteoclastic bone resorption followed by replacement of bone in a chaotic fashion.

Paracrine A type of hormone function in which hormone synthesized in and released from endocrine cells binds to its receptor in nearby cells of a different type and affects their function.

Paraganglioma A tumor of the tissue composing the paraganglia.

Parallel analysis Type of analysis in which all specimens are subjected to a series of analytical processes at the same time and in a parallel fashion.

Parametric analysis A statistical approach to reference value analysis that requires specific distributional assumptions. For example, it usually requires that the distribution of values be Gaussian (or that the values be mathematically manipulated so that they become Gaussian).

Paraprotein A monoclonal immunoglobulin produced in excessive amounts in disorders such as multiple myeloma.

Parathyroid hormone (PTH) The hormone secreted by the parathyroid glands that controls the concentration of calcium in the blood.

Parathyroid hormone–related protein (PTHrP) A protein that mimics many actions of PTH, but is a product of a different gene that is expressed in many normal tissues and overexpressed by tumors in most cases of humoral hypercalcemia of malignancy (HHM).

Parkinson disease A slowly progressive disorder affecting the basal ganglia, usually occurring in late life, with an average age of onset of 60 years.

Paroxysmal nocturnal hemoglobinuria (PNH) Disease of the blood characterized by complement-induced intravascular hemolytic anemia, red colored urine, and thrombosis.

Partial pressure The substance (mole) fraction of gas times the total pressure; i.e., the partial pressure of oxygen, $P O_2$, is the fraction of oxygen gas times the barometric pressure.

Partin tables A statistical model developed by Alan W. Partin, M.D., Ph.D. at the Johns Hopkins University School of Medicine that shows the probability that the cancer is confined to the prostate and likely to be cured with surgery.

Partition chromatography A separation mechanism that is based on the differential distribution of solutes between two immiscible liquids.

Partitioning The use of specific criteria in the subclassification of reference groups to reduce the biological variation in each group; the most commonly used criteria are age and sex.

Peak concentration The highest concentration achieved within the dosing cycle.

Pellagra A clinical deficiency syndrome due to deficiency of niacin (or failure to convert tryptophan to niacin) and characterized by dermatitis, inflammation of mucous membranes, diarrhea, and psychic disturbances.

Pendrin A protein that is mutated in Pendred syndrome, which is an autosomal recessive disorder characterized by (1) sensorineural hearing loss, (2) goiter, and (3) a partial organification problem. Also known as the sodium-independent chloride/iodide transporter.

Peptic ulcer disease The collective name given to duodenal and gastric ulceration.

Peptide A compound consisting of two or more amino acids linked in a chain via peptide bonds.

Peptide bond The amide bond formed between the carboxyl group of one amino acid and the amino group of another.

Peptide nucleic acid (PNA) An artificially synthesized polymer similar to DNA or RNA. The term is somewhat of a misnomer, because PNA is not an acid.

Percutaneous coronary intervention (PCI) The management of coronary artery occlusion by any of various catheter-based techniques.

Peritoneal dialysis (PD) Diffusion of solutes and convection of fluid through the peritoneal membrane. The dialyzing solution is introduced into and removed from the peritoneal cavity as either a continuous or an intermittent procedure.

Pernicious anemia A deficiency in the production of red blood cells through a lack of vitamin B12.

pH A measure of acidity and alkalinity of a solution. (The negative logarithm of hydrogen ion activity.)

Pharmaceutical drug Any chemical substance intended for use in the (1) medical diagnosis, (2) cure, (3) treatment, or (4) prevention of disease. Also referred to as a medicine or medication.

Pharmacodynamics A process that defines how a drug acts on its target and its mechanisms of action.

Pharmacogenetics (PD) Study of the variations in single genes or small groups of related genes that affect the response to a drug, including its metabolism.

Pharmacogenomics The study of the inherited variations in genes that dictate drug response and the way these can be used to predict individual responses to a drug, using a genome-wide approach.

Pharmacogenomics Knowledge Base (PharmGKB) An integrated resource about how variation in human genetics leads to variation in response to drugs; database of information about genes (pharmacogenes) involved in modulating the response to drugs.

Pharmacokinetics (PK) A process describing how a drug is (1) absorbed, (2) distributed, (3) metabolized, and (4) eliminated.

Phencyclidine A potent veterinary analgesic and anesthetic, sometimes used as a drug of abuse by humans but capable of causing serious psychological disturbances.

Phenocopying The alteration of a phenotype through a nongenetic, environmental mechanism.

Phenotype The observable physical or biochemical characteristics of an individual, as determined by their genetic makeup and environmental influences.

Phenotyping Laboratory testing designed to measure or predict the reaction or response of an individual to a stimulus (such as, a specific drug). A drug-related phenotype is based upon an individual's genes, but it is also influenced by non-genetic factors, such as concomitant medications, liver function, and renal function.

Phenylketonuria (PKU) A disorder characterized by the accumulation of phenylalanine in blood that results from the absence of phenylalanine hydroxylase activity leading to production of phenylketones that are excreted in urine.

Pheochromocytoma A usually benign, well-encapsulated, lobular, vascular tumor of chromaffin tissue of the adrenal medulla or sympathetic paraganglia.

Philadelphia chromosome An abnormality of chromosome 22 present in marrow cells of most patients with chronic granulocytic leukemia. It is generally a reciprocal translocation between chromosomes 9 and 22 that results in expression of a fusion gene (called BCR-ABL) that acts as an oncogene.

Phlebotomist One who practices phlebotomy; the individual drawing a specimen of blood.

Phlebotomy The puncture of a blood vessel to collect blood; literally, "the letting of blood in the treatment of disease."

Phospholipase C Any esterase that catalyzes the hydrolysis of the phosphoric ester bond of a membrane phospholipid, generating a phosphorylated alcohol and diacylglycerol.

Phospholipid A polar amphipathic lipid located on the surface of a lipoprotein; phospholipids are also found at the aqueous interface of biological membranes.

Photometry/Spectrophotometry The measurement of the luminous intensity of light or the amount of luminous light falling on a surface from such a source; spectrophotometry is the measurement of the intensity of light at selected wavelengths.

Pilocarpine iontophoresis Noninvasive method that uses electricity to force the drug pilocarpine into the skin for the purpose of inducing sweating at the site.

Pipette Device used for the transfer of a volume of liquid from one container to another.

Pituitary dwarfism Short stature caused by decreased synthesis or action of growth hormone.

Pituitary gigantism Excessive growth caused by increased synthesis of growth hormone before the epiphyses have fused.

Pituitary gland An elliptical body located at the base of the brain and attached by a stalk to the hypothalamus, from which it receives important neural and vascular outflow. It is divided into the anterior (adenohypophysis) and posterior (neurohypophysis) pituitary with each responsible for the production of its own unique hormones.

Placenta A membranous vascular organ that develops in female mammals during pregnancy, lining the uterine wall and partially enveloping the fetus, to which it is attached by the umbilical cord. Following birth, the placenta is expelled. Its functions include (1) transport of nutrients to the fetus, (2) transport of waste from the fetus, and (3) exchange of gases (oxygen and carbon dioxide) between the mother and fetus.

Placental alpha microglobulin-1 (PAMG-1) A protein present in blood and the amniotic fluid and cervico-vaginal discharge of pregnant women.

Planar chromatography A separation technique in which the stationary phase is on a thin support such as paper or a glass plate.

Plasma The noncellular component of anticoagulated whole blood; plasma contains clotting factors.

Plasma proteins Proteins present in blood, including carrier proteins, fibrinogen and other coagulation factors, complement components, immunoglobulins, enzyme inhibitors,

and many others; most are found in other body fluids but in lower concentrations.

Plasmid An extrachromosomal ring of double-stranded, closed DNA found in bacteria.

Pneumoconiosis Deposition of large amounts of dust or other particulate matter in the lungs.

Point-of-care testing (POCT) Clinical testing that occurs next to the patient, usually with a handheld device and an unprocessed specimen collected immediately before testing.

Poison Any substance that, when relatively small amounts are ingested, inhaled, or absorbed, or when it is applied to, injected into, or developed within the body, has chemical action that may cause damage to structure or disturbance of function, producing symptoms, illness, or death.

Polycystic kidney disease The most common renal cystic condition, with deterioration of renal function.

Polycystic ovary syndrome (PCOS) A female condition that is characterized by multiple ovarian follicles and increased androgen production.

Polydipsia Chronic excessive intake of water as in diabetes mellitus or diabetes insipidus.

Polyhydramnios (or hydramnios) The presence of excess amniotic fluid.

Polymerase chain reaction (PCR) An in vitro method for exponentially amplifying DNA.

Polymerases Enzymes that sequentially add nucleotides onto a growing polynucleotide, usually requiring a primer and a template.

Polyuria The passage of a large volume of urine in a given period.

Population In relation to analytical methods, the complete set of all observations that might occur as the result of performing a particular procedure according to specified conditions.

Porphobilinogen (PBG) Immediate precursor of the porphyrins; a pyrrole ring with acetyl, propionyl, and aminomethyl sidechains; four molecules of PBG condense to form one molecule of 1-hydroxymethylbilane, which is then converted successively to uroporphyrinogen-III, coproporphyrinogen-III, protoporphyrinogen-IX, protoporphyrin-IX, and heme.

Porphyria cutanea tarda (PCT) The most common form of porphyria, characterized by cutaneous photosensitivity. Porphyrin precursors ALA and PBG, the biosynthetic intermediates, are metabolized to porphyrinogens and porphyrins.

Porphyrias A group of mainly inherited metabolic disorders that result from partial deficiencies of the enzymes of heme biosynthesis, which cause increased formation and excretion of porphyrins, their precursors, or both.

Porphyrins Any of a group of compounds containing the porphyrin structure; four pyrrole rings connected by methylene bridges in a cyclical configuration, to which a variety of sidechains are attached.

Portal hypertension Any increase in the pressure in the portal vein (which carries venous blood from the intestines and spleen to the liver) due to anatomical or functional obstruction (for example, cirrhosis) to blood flow in the portal venous system.

Postgastrectomy syndrome A syndrome following surgery for peptic ulcer disease that includes the dumping syndrome, diarrhea, maldigestion, weight loss, anemia, bone disease, and gastric cancer.

Potential difference The work required to move an electrical charge and measured in volts.

Potentiometry An electrochemical technique that measures an electrical potential difference between two electrodes (half-cells) in an electrochemical cell.

Preanalytical errors Factors that affect specimens before tests are performed and that can lead to error if not controlled; they are classified as controllable or uncontrollable.

Precocious puberty Early development of secondary sex characteristics; in girls generally before age 8 and in boys before age 9.

Predictive value The predictive value of a positive laboratory test is the number of true positive results divided by the total number of positive results (true positives plus false positives); the negative predictive value is the number of true negative results divided by the total number of negative results (true negatives plus false negatives).

Predictive value of a negative test The proportion of subjects with a negative test who do not have the disease.

Predictive value of a positive test The proportion of subjects with a positive test who have the disease.

Preeclampsia A disorder of widespread vascular endothelial malfunction and vasospasm that occurs after 20 weeks gestation and can present as late as 4 to 6 weeks postpartum. It is clinically defined by hypertension and proteinuria, with or without pathologic edema.

Pregnancy The period from conception to birth. It usually lasts 40 weeks, beginning from the first day of the woman's last menstrual period (LMP), and is divided into three trimesters, each lasting 3 months.

Pregnancy-associated plasma protein A (PAPP-A) A protein used in screening tests for Down syndrome.

Premature rupture of membranes (PROM) Breakage of the sac containing the developing fetus and the amniotic fluid prior to the start of labor; rupture before the 37th week of gestation is called preterm PROM (PPROM).

Preservative A substance or preparation added to a specimen to prevent changes in the constituents of a specimen.

Preterm delivery The birth of an infant before 37 weeks gestation.

Prevalence The frequency of disease in the population examined.

Primary biliary cirrhosis (PBC) A rare form of liver disease that results in the irreversible destruction of the small bile ducts within the liver.

Primary hypothyroidism A condition that develops when the thyroid gland fails to produce or secrete as much thyroxine (T_4) as the body needs.

Primary ovarian insufficiency (POI) A condition in which the ovary fails to function adequately in a woman younger than 40 years.

Primary sclerosing cholangitis (PSC) A chronic, nonbacterial inflammatory narrowing of the bile ducts (usually the larger ducts outside of the liver).

Primer An oligonucleotide that serves to initiate polymerase-catalyzed addition of nucleotides by annealing to a template strand.

Probe A nucleic acid used to identify a target by hybridization.

Procollagen type I carboxy-terminal propeptide (PICP) A biochemical marker of bone formation.

Procollagen type I N-terminal propeptide (PINP) A biochemical marker of bone formation.

Prodrug A drug that is administered in an inactive or poorly-active form and is converted to an active drug by metabolism.

Product The substance produced by the enzyme catalyzed conversion of a substrate.

Product ion A fragment ion formed when a molecular ion breaks into smaller pieces; in a tandem mass spectrometer, the fragmentation process takes place after ions have been separated by the m/z value in a first stage of mass spectrometry.

Proficiency testing (PT) A process in which simulated patient specimens made from a common pool are analyzed by laboratories to determine the "quality" of laboratories' performance; considered to be part of external quality assessment.

Progestational Preceding or promoting pregnancy; the phase of the menstrual cycle after ovulation; related to the characteristic actions of progesterone.

Progesterone The principal progestational hormone liberated by the (1) corpus luteum, (2) adrenal cortex, and (3) placenta, whose function is to prepare the uterus for the implantation and development of the fertilized oocyte.

Prognosis A prediction of the future course and outcome of a patient's disease based on currently known indicators (e.g., age, sex, tumor stage, tumor marker level).

Proinsulin A precursor of insulin, with a molecular weight of 8,000 to 10,000; it has minimal hormonal activity and is converted to insulin by removal of the connecting C peptide, leaving the two (A and B)-chain, active insulin molecule.

Prokaryote Organisms (such as bacteria) that are characterized by the absence of a distinct, membrane-bound nucleus or membrane-bound organelles and by DNA that is not organized into chromosomes.

Prolactin A pituitary hormone that stimulates and maintains the secretion of milk.

Prolactin-inhibiting hormone A hormone released by the hypothalamus that inhibits secretion of prolactin by the adenohypophysis. Also known as prolactin-inhibiting factor and prolactostatin.

Promoter A regulatory region of DNA that serves to bind RNA polymerase II that in turn binds other substances that will lead to initiation of transcription; promoters and the substances that bind to them control the rate and timing of tRNA synthesis and thus of synthesis of the coded protein.

Pro-opiomelanocortin (POMC) The 31,000 dalton prohormone that is the precursor of corticotropin, the lipotropins, the melanocyte-stimulating hormones, and the endorphins, all of which are produced by posttranslational proteolytic cleavage of POMC in cell types that produce these hormones.

Propionic acidemia An organic acid disorder due to deficiency of an enzyme involved in amino acid and fatty acid catabolism. It is characterized by excess of propionic acid in the blood and urine.

Prostaglandin Any of a group of compounds derived from unsaturated 20-carbon fatty acids (primarily arachidonic acid) via the cyclo-oxygenase pathway; these compounds are involved in a number of physiological processes.

Prosthetic group A tightly-bound, non-peptide structure required for the activity of an enzyme.

Protein A polymer of amino acids linked by peptide bonds with a specific sequence that folds into a defined structure; any of a group of complex organic compounds that contain carbon, hydrogen, oxygen, nitrogen, and usually sulfur (the characteristic element being nitrogen).

Proteinuria Excessive serum proteins in the urine, such as in renal disease, after strenuous exercise, and with dehydration.

Proteome The total complement of proteins expressed by the genetic material of an organism under a given set of environmental conditions.

Proteomics The identification and quantification of proteins and their posttranslational modifications in a given system or systems.

Protoporphyrin A porphyrin with four methyl, two vinyl, and two propionic acid sidechains attached to the tetrapyrrole backbone.

Pseudogene A genetic element that does not code for a functional gene product, usually because of accumulated sequence variations.

Pseudohermaphroditism The condition of having the gonads and karyotype of one sex and external genitalia that is of the other sex or is ambiguous.

Pseudohypoaldosteronism type 1 (PHA1) A hereditary disorder of infancy characterized by severe salt wasting, failure to thrive, and other signs of aldosterone deficiency.

Pseudoprecocious puberty Development of secondary sex characters and reproductive organs that is not associated with pubertal levels of gonadotropins and gonadotropin-releasing hormone. Also called GnRH-independent precocious puberty.

Puerperium The approximate 6-week period lasting from childbirth to the return of normal uterine size.

Pulmonary surfactant A fluid secreted by the cells of the alveoli that serves to reduce the surface tension of pulmonary fluids.

Pure gonadal dysgenesis An intersex disorder characterized by 46 XX chromosomes and normal external female genitalia at birth.

Purine A base containing two carbon-nitrogen rings; adenine and guanine are purines.

Pyelonephritis An inflammation of the kidney and its pelvis as a result of infection.

Pyridium crosslinks A family of molecules that links collagen molecules to each other; the breakdown products are excreted in the urine with attached crosslinks including-pyridinoline (PYD) and deoxypyridinoline (DPD).

Pyrimidine A base containing one carbon-nitrogen ring; cytosine, thymine, and uracil are pyrimidines.

Pyrosequencing A method of DNA sequencing based on the "sequencing by synthesis" principle that relies on the detection of pyrophosphate (PPi) release on nucleotide incorporation.

Pyruvate An organic acid formed from glucose through glycolysis.

Quality assessment A quality laboratory process that is concerned primarily with broader measures and monitors of laboratory performance such as turnaround times and test utility.

Quality Conformance to the requirements of users or customers and the satisfaction of their needs and expectations.

Quality control A quality laboratory process that involves statistical analysis of internal control procedures through use of control materials for method performance assessment and nonstatistical check procedures such as linearity studies and reagent checks.

Radial immunodiffusion An immunodiffusion technique used to determine the quantity of an antigen by measuring the diameters of circles of precipitin complexes surrounding samples of the antigen.

Random error Error that arises from imprecision of measurement of the type that is described by a Gaussian distribution (e.g., caused by pipetting variability, signal variability).

Random-access analysis T e most common configuration of an automated analyser, in which analyses are performed on a collection of specimens sequentially and each specimen is analyzed for a different selection of tests.

Randomized controlled trial An experimental study in which study participants are randomly allocated to an intervention (treatment) group or an alternative treatment (control) group.

Rapid plasma reagin test (RPR test) Any of a group of serologic tests for syphilis.

Rapidly progressive glomerulonephritis Acute glomerulonephritis marked by a rapid progression to end-stage renal disease.

Reaction cell T e location in a point-of-care testing device where the analytical reaction takes place.

Reagent Chemical used in many high-purity applications.

Real-time PCR Observation of PCR during amplification at least once each cycle.

Receiver operating characteristic plot A graph of sensitivity versus 1 minus specificity for all possible cutoff values of a diagnostic test; used to display sensitivity and specificity for various decision cutoffs.

Receptor A molecular structure within a cell or on the surface characterized by (1) selective binding of a specific substance and (2) a specific physiological effect that accompanies the binding; examples include cell surface receptors for peptide hormones, neurotransmitters, antigens, complement fragments and immunoglobulins, and cytoplasmic receptors for steroid hormones.

Recognition element A chemosensor with a transducing element that recognizes the analyte to be measured and produces a signal.

Recombination T e process of exchange of genes or segments of DNA between chromosomes; recombination produces gametes with chromosomes that are different from the parent's. Recombination of DNA segments is also done in the laboratory as a step in producing recombinant proteins. (see CentiMorgan.)

Recommended dietary allowance (RDA) T e amount of nutrient and calorie intake per day considered necessary for maintenance of good health, calculated for males and females of various ages and recommended by the Food and Nutrition Board of the U.S. National Research Council. Popularly called recommended daily allowance.

Redox couple A conjugate pair of substances that consists of any substance that accepts electrons (the oxidant) and any substance that donates electrons (the reductant); redox processes take place only between two redox couples, with electrons transferred from a reductant to an oxidant.

Reference individual An individual selected as the basis for comparison with individuals under clinical investigation through the use of defined criteria.

Reference interval (population-based) A set of values usually defined by an upper reference limit and a lower reference limit, representing a specified proportion of the reference population; this is frequently the central 95% of values from the reference population.

Reference interval (subject-based) A set of values usually defined by an upper reference limit and a lower reference limit, representing a specified proportion of the values from a reference individual; this is frequently the central 95% of values from the reference individual.

Reference material A material or substance, one or more physical or chemical properties of which are suf ciently well established to be used for the calibration of an apparatus, the verification of a measurement method, or the assigning of values to materials. Certified, primary, and secondary are types of reference materials.

Reference measurement procedure A procedure of highest analytical quality that has been shown to yield values having an uncertainty of measurement commensurate with its intended use, especially in assessing the trueness of other measurement procedures for the same quantity and in characterizing reference materials.

Reference population An undefined number of individuals that represent the demographic for which the reference intervals will be used. Reference individuals are chosen, preferably at random, from this larger population to provide reference samples for the establishment of a reference interval.

Reference value A value obtained by observation or measurement of a particular type of quantity on a reference individual; results of a certain type of quantity obtained from a single individual or group of individuals corresponding to a stated description.

Reflectance photometry A spectrophotometric technique in which diffused light illuminates a reaction mixture in a carrier containing a substance of interest, and the intensity of the reflected light is measured.

Regan isoenzyme Isoenzyme of alkaline phosphatase that has been observed in the plasma of patients with malignant tumors.

Regression analysis A statistical analysis that compares measurement relations between two analytical methods.

Relative centrifugal force or field (RCF) Force required to separate two phases (liquid and solid) in a centrifuge.

Renal clearance T e volume of plasma from which a given substance is completely cleared by the kidneys per unit of time.

Renal osteodystrophy Bone diseases associated with chronic renal failure, including high turnover (osteitis fibrosa or secondary hyperparathyroidism) and low turnover (osteomalacia and adynamic bone) diseases.

Renal replacement therapy (RRT) Any treatment that replaces kidney function, including dialysis and transplantation.

Renal tubular acidosis (RTA) A variety of metabolic acidosis resulting from impairment of renal function.

Renin An enzyme of the hydrolase class that catalyzes cleavage of the leucine-leucine bond in angiotensinogen to generate angiotensin I.

Replication T e faithful reproduction of the DNA content from parent to daughter cells during cell division.

Resolution A measure of the separation of two adjacent chromatographic peaks; resolution equals the difference in retention time for two components divided by the average of their peak widths.

Respiratory acidosis A pathological process that leads to the accumulation of carbon dioxide that raises the P CO_2 and decreases the pH; usually caused by emphysema or hypoventilation.

Respiratory alkalosis A pathological process that leads to the excessive elimination of carbon dioxide which lowers the P CO_2 and increases the pH; caused by hyperventilation.

Respiratory distress syndrome (RDS) A disease of premature infants caused by a deficiency of lung surfactant.

Restriction endonuclease An endonuclease that cuts nucleic acid in a sequence-specific manner.

Restriction fragment length polymorphism (RFLP) A genetic polymorphism revealed by changes in the sizes of DNA fragments after restriction enzyme digestion and electrophoresis.

Retention time T e time interval between specimen injection and solute reaching the detector; retention time helps identify and quantify analyte.

Retrovirus A family of RNA viruses containing a reverse transcriptase enzyme that allows the viruses' genetic information to become part of the genetic information of the host cell upon replication.

Reverse T_3 (rT_3) A biologically inert metabolite of thyroxine (T_4) with three iodine molecules attached in a configuration (L-3,3′,5′-triiodothyronine) different from that of the active thyroid hormone triiodothyronine (T_3).

Reverse transcriptase A polymerase that catalyzes synthesis of DNA from an RNA template.

Reversed-phase chromatography A partitioning type of chromatography in which the mobile phase is polar relative to the nonpolar stationary phase.

Reye syndrome A sudden, sometimes fatal, disease of the brain (encephalopathy) caused by specific forms of acute injury to the liver.

Ribonucleic acid (RNA) A biological substance similar to DNA with the exceptions of being single stranded, containing ribose as the sugar moiety, having an extra hydroxyl group, and containing uracil instead of thymine; there are different functional types of RNA, including messenger (coding) RNA (mRNA), ribosomal RNA (rRNA), transfer RNA (tRNA), and other small noncoding RNAs (ncRNAs), such as microRNA (miRNA).

Ribosome A large molecular structure comprised of ribosomal RNA and protein that is found in the cytoplasm of cells that serves as the site of protein synthesis.

Rickets A disorder in children caused by a lack of vitamin D, calcium, or phosphate that leads to softening and weakening of the bones. In adults it is known as osteomalacia.

Risk stratification A statistical process used to determine detectable characteristics associated with an increased chance of experiencing unwanted outcomes.

Rolling circle amplification (RCA) A probe amplification method where, in the presence of template, a linear probe is ligated to form a circle that is replicated continuously by a polymerase and one or more primers.

Rotor syndrome A type of chronic familial nonhemolytic jaundice that differs from Dubin-Johnson syndrome in the lack of liver pigmentation.

Sanger sequencing A method of DNA sequencing based on the selective incorporation of chain-terminating dideoxynucleotides by DNA polymerase during in vitro DNA replication. Also known as dideoxy-termination sequencing.

SARA Superfund Amendments and Reauthorization Act. T e Superfund Amendments and Reauthorization Act (SARA) amended the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) on October 17, 1986.

Screening test An initial test that is used to "screen" specimens to eliminate "negative" ones from further consideration and to identify presumptively positive specimens that then require confirmatory testing.

Scurvy A condition due to deficiency of ascorbic acid (vitamin C) in the diet.

Second messenger Any of several classes of intracellular signals that translate electrical or chemical messages from the environment (first messengers) into cellular responses.

Secondary hyperparathyroidism Excessive secretion of parathyroid hormone (PTH) in response to low plasma calcium that, in turn, is caused by another condition; seen in patients with chronic renal failure and in people with inadequate vitamin D.

Secondary hypothyroidism Hypothyroidism that arises as a consequence of inadequate secretion of thyroid stimulating hormone (TSH or thyrotropin) by the anterior pituitary gland.

Secretin A peptide hormone of the gastrointestinal (GI) tract (27 amino acids) found in the mucosal cells of the duodenum. Among its multiple functions, secretin increases water and bicarbonate secretion to buffer the incoming protons of the acidic chyme. It has considerable homology with GIP, vasoactive intestinal polypeptide (VIP), and glucagon.

Sedative A drug that depresses activity of the central nervous system and reduces anxiety and induces sleep.

Selected ion monitoring (SIM) A MS technique where only specified ions of interest are monitored.

Selection criteria A set of criteria that define the desired characteristics of a reference individual. T e specific criteria chosen will depend of the purpose of the reference interval and the specific population the RI is intended to represent.

Self-monitoring of blood glucose (SMBG) A procedure whereby diabetic patients collect their own blood specimens, which are then analyzed for their glucose content.

Sensitivity T e proportion of subjects with disease who have a positive laboratory test result.

Sensor A component of a point-of-care testing device that identifies a signal produced by the presence of an analyte.

Sequencing Any method that determines the exact order of bases in a DNA fragment.

Sequential analysis Type of analysis in which each specimen in a batch enters the analytical process one after another, and each result or set of results emerges in the same order as the specimens are entered.

Serial invasive signal amplification A signal enhancing technique that combines two invasive signal amplification reactions in series in a single-tube format.

Seroconversion Development of antibodies in blood serum as a result of infection or immunization.

Serotonin (5-hydroxytryptamine) A monoamine vasoconstrictor synthesized in the intestinal enterochromaf n cells or in central or peripheral neurons; found in high concentrations in many body tissues, including intestinal mucosa, pineal body, and central nervous system.

Sertoli cell Any of the elongated, striated cells of the seminiferous tubules of the testis, to which spermatids attach for nourishment during spermatogenesis.

Sertoli cell–only syndrome A condition characterized by congenital absence of germinal epithelium from the seminiferous tubules, which contain only Sertoli cells, resulting in sterility due to the absence of living sperm cells in the semen. Also called Del Castillo syndrome.

Serum T e watery portion of blood that remains after coagulation has occurred; it is obtained after centrifugation.

Severe cutaneous adverse reaction syndromes (SCARS) A group of serious skin conditions that are characterized by blisters and epidermal detachment.

Sex hormone binding globulin (SHBG) A glycoprotein that binds to sex hormones, specifically androgens and estrogens.

Sharps Any object which could readily puncture or cut the skin of an individual when encountered.

Sharps container A container designed for the disposal of sharps; required and regulated by the Occupational Safety and Health Administration (OSHA).

Short tandem repeats (STRs) Short segments of DNA (1 to 13 bases long) that are repeated end to end. Also known as microsatellites.

Sick euthyroid syndrome Abnormalities of T_4, free T_4, T_3, and TSH concentrations that are seen in people with severe illness. In general, treatment with replacement thyroid hormone is not indicated.

Sickle cell anemia An autosomal dominant type of hemolytic anemia that is caused by the presence of hemoglobin S with abnormal sickle-shaped erythrocytes (sickle cells).

Side chain A chemical group that is attached to a core part of the molecule.

Signal amplification Any method that increases the signal resulting from a molecular interaction that does not involve target amplification or probe amplification.

Simple sequence repeats (SSRs) Any sequence repeated over and over again in tandem, such as microsatellites and minisatellites.

Single-base primer extension (SBE) assay An assay performed by annealing a primer to ssDNA immediately adjacent to the single base variant.

Single-channel analysis Type of analysis in which each specimen is subjected to a single process so that only results for a single analyte are produced; similar to batch analysis.

Single-nucleotide polymorphism (SNP) A benign single-nucleotide variant (SNV) (substitution, deletion, or insertion) that occurs in the population at a frequency of at least 1%.

Single-nucleotide variant (SNV) Any change in a nucleic acid that involves only a single nucleotide, including base changes, and single base deletions/ insertions. Now favored over the related term "single nucleotide polymorphism" (SNP) and not limited to variants present at a frequency of >1% as is SNP. SNVs may be benign or may cause disease.

Single-stranded conformational polymorphism (SSCP) A gel electrophoresis technique where single-stranded DNA (ssDNA) segments are identified by their abnormal migration patterns.

Six Sigma process control A quantitative framework for evaluating process performance and providing more objective evidence for process improvement, with a goal of having Six Sigmas or six standard deviations of process variation fitting within the tolerance limits of the process.

Size-exclusion chromatography A separation mechanism that separates solutes on the basis of the molecular size of the solutes in a solution.

Sjögren syndrome A systemic autoimmune disease in which immune cells attack and destroy the glands that produce tears and saliva.

Skimmer A cone with a central orifice that is designed to intercept the center of a spray or jet expansion so as to sample the central portion of the expansion.

Skin puncture Collection of capillary blood usually from a pediatric patient by making a thin cut in the skin, usually at the heel of the foot.

Smith-Lemli-Opitz syndrome (SLOS) A congenital malformation syndrome caused by deficiency of the enzyme 7-dehydrocholesterol reductase (DHCR7), due to mutation of the DHCR7 gene on chromosome 11.

Sodium–hydrogen exchanger (NHE) A membrane protein that is primarily responsible for maintaining the balance of sodium; also called the sodium–hydrogen antiporter.

Somatostatin Any of several cyclic tetradecapeptides produced in the hypothalamus that inhibit release of several hormones of the pituitary.

Southern blot A method for detecting DNA sequence variants after restriction enzyme digestion and size separation by electrophoresis.

Speciation methods Techniques used to separate the chemical complexes of individual elements present in any particular medium.

Specificity The proportion of subjects without disease who have a negative laboratory test result.

Specimen A sample or portion of body fluid or tissue collected for examination, study, or analysis.

Spectral bandwith The width in nanometers of the spectral transmittance curve at a point equal to one-half of the peak transmittance; used to describe the spectral purity of a filter or other monochromator.

Sperm protein SP-10 A sperm acrosomal protein, specific to the testis, that is believed to play an important role in egg-sperm binding.

Spina bifida A congenital disorder caused by the incomplete closure of the embryonic neural tube (see neural tube defect); the most common form is meningomyelocele (also called myelomeningocele).

Spliceosome A large ribonucleoprotein complex, composed of various small nuclear ribonucleoproteins (snRNP) as well as other protein factors; it attaches to specific sites on pre-mRNA and catalyzes splicing out of their introns in the formation of mature mRNA.

Sprue A chronic form of malabsorption syndrome occurring in tropical and nontropical forms.

ST segment elevation myocardial infarction (STEMI) Any type of myocardial infarction in which the ST segment is elevated in one lead or several leads of the EKG.

Star (*)-allele nomenclature A nomenclature developed to standardize genetic polymorphism annotation for the cytochrome P_{450} genes.

STARD Standards for Reporting of Diagnostic Accuracy; a project designed to improve the quality of reporting of the results of diagnostic accuracy studies.

Stationary phase A solid or a liquid phase that interacts with components of the mobile phase.

Steatorrhea A condition of excessive fat in feces (more than 5 g/day).

Stereoisomer One of a group of compounds differing only in the spatial arrangement of their atoms.

Steroidogenesis The biosynthesis of steroids by the adrenal glands and gonads.

Steroidogenic acute regulatory protein (StAR) A transport protein that functions to regulate cholesterol transfer within the mitochondria.

Stevens-Johnson syndrome (SJS) A serious allergic reaction with a characteristic rash involving the skin and mucous membranes. The hypersensitive (allergic) reaction may be initiated by drugs, infectious agents, or other stimuli.

Strand displacement amplification (SDA) An amplification technique that uses two types of primers and DNA polymerase and restriction endonuclease to exponentially produce single-stranded amplicons asynchronously.

Subclinical hyperthyroidism A biochemical condition with normal concentrations of serum thyroid hormones when the serum TSH concentration is repeatedly low in the absence of hypothalamic or pituitary disease.

Substrate A reactant in an enzyme-catalyzed reaction that binds to the active center of an enzyme.

Superfund A program of the U.S. Government to clean up the nation's uncontrolled hazardous waste sites. Under the Superfund program, abandoned, accidentally spilled, or illegally dumped hazardous waste that poses a current or future threat to human health or the environment is cleaned up.

Superoxide dismutase An enzyme of the oxidoreductase class that catalyzes the reduction of superoxide anions to hydrogen peroxide, protecting cells against dangerous levels of superoxide (oxygen).

Survivin A protein that neutralizes caspase activity and thus inhibits apoptosis, expressed during the G2/M phase of the cell cycle in many tumors but not in most normal differentiated adult tissues.

Sweat chloride The concentration of chloride in sweat; increased sweat chloride is characteristic of cystic fibrosis.

Syndrome of inappropriate antidiuretic hormone (SIADH) A condition in which inappropriate antidiuretic hormone secretion produces dilutional hyponatremia, and increased extracellular fluid volume with an elevated urine osmolality.

Systematic error Error in measurement that arises from calibration bias or nonspecificity of an assay and, in the course of a number of analyses of the same analyte, remains constant (y-intercept deviation from zero) or varies in a proportional way (slope deviation from unity) based on the analyte concentration.

Systematic review A methodical and comprehensive review of all published and unpublished information about a specific topic to answer a precisely defined clinical question.

Systemic inflammatory response syndrome (SIRS) The systemic inflammatory response to a wide variety of severe clinical insults.

Systemic lupus erythematosus (SLE or lupus) A condition that can affect any part of the body.

T_3 Thyrotoxicosis A hyperthyroid condition in which T_3 but not T_4 is elevated.

Tandem mass spectrometer A mass spectrometer capable of successive separation of ions in an ion beam according to m/z value (tandem in space) or separation of a set of trapped ions in an ion trap according to m/z value (tandem in time).

Tandem mass spectrometry (MS/MS) A spectrometric method of analysis where two mass spectrometers are connected in series. It involves separation and identification of substances and chemicals based on their mass to charge (m/z) ratio.

Target amplification Any method for increasing the amount of target nucleic acid. A target-specific primary reaction is used to drive a secondary invasive reaction.

Tartrate-resistant acid phosphatase 5b (TRACP5b) An enzyme derived from osteoclasts; it is a marker of bone resorption.

Telomere The DNA sequences at the end of a chromosome; telomeres contain repetitive nucleotide sequences that protect the ends of chromosomes from recombination with other chromosomes.

Temperature-gradient gel electrophoresis (TGGE) A form of electrophoresis that uses temperature to denature the sample as it moves across an acrylamide gel.

Template A nucleic acid molecule the sequence of which serves as a pattern to be copied by a polymerase to produce a DNA or RNA with a complementary sequence.

Testis The male gonad, either of two oval reproductive glands located in the scrotum.

Testosterone The principal androgenic hormone, produced by the Leydig cells of the testes in response to stimulation by LH from the anterior pituitary gland.

Thalassemia A heterogeneous group of hereditary hemolytic anemias having a decreased rate of synthesis of one or more hemoglobin polypeptide chains and classified according to the chain involved (α, β, δ); the two major categories are α- and β-thalassemia.

Thalassemia major The homozygous form of β-thalassemia, a severe condition evident from the neonatal period with complete absence of hemoglobin A.

Thalassemia minor The heterozygous form of β-thalassemia; it is usually asymptomatic, although hemoglobin A synthesis may be retarded and there is sometimes moderate anemia and splenomegaly.

Therapeutic drug monitoring/management (TDM) A process used to measure blood drug levels so that the most effective dosage is maintained and toxicity prevented.

Therapeutic range The interval between the minimum and maximum doses of a drug.

Thermocycler A laboratory apparatus used in the amplification of segments of DNA via the PCR. Often, the device has a thermal block with holes where tubes holding the reaction mixtures are inserted. The cycler then raises and lowers the temperature of the block in discrete, preprogrammed steps.

Thermus aquaticus (Taq) A thermostable DNA polymerase named after the thermophilic bacterium Thermus aquaticus. It is often abbreviated to "Taq Pol" or "Taq" and is frequently used in PCR.

Thiopurine S-methyltransferase (TPMT) A metabolic enzyme that methylates and thereby inactivates certain antimetabolites, such as 6-mercaptopurine (6-MP) (cancer therapeutic).

Threshold limit value (TLV) The maximum concentration of a chemical allowable for repeated exposure without producing adverse health effects.

Thrombolysis Lysis of a thrombus or thrombi.

Throughput The number of specimens processed by an analyzer during a given period of time, or the rate at which an analytical system processes specimens.

Thyroglobulin (Tg) An iodine-containing glycoprotein of high molecular weight (663 kDa) present in the colloid of the follicles of the thyroid gland.

Thyroid follicle The secretory unit of the thyroid gland consisting of an outer layer of epithelial cells that enclose an amorphous material called colloid.

Thyroid storm A life-threatening condition that develops in a minority of cases of untreated thyrotoxicosis (hyperthyroidism, or overactive thyroid).

Thyroiditis A condition characterized by inflammation of the thyroid gland.

Thyroid-stimulating hormone (TSH) A polypeptide hormone synthesized by the anterior pituitary gland that promotes the growth of the thyroid gland and stimulates the synthesis and release of thyroid hormones by the thyroid gland. Also called thyrotropin.

Thyrotoxicosis A toxic condition resulting from excessive amounts of thyroid hormones in the body.

Thyrotropin A glycoprotein hormone synthesized by the anterior pituitary gland that promotes the growth of the thyroid gland and stimulates the hormonal secretion by the gland. Also called thyroid-stimulating hormone.

Thyrotropin-releasing hormone (TRH) A tripeptide produced in the hypothalamus that stimulates the release of TSH from the anterior pituitary.

Thyroxine (T_4) The major hormone synthesized and released by the thyroid gland that contains four iodine molecules (L-3,5,3′,5′-tetraiodothyronine).

Tiling arrays A subtype of microarray that functions by hybridizing labeled DNA or RNA target molecules to probes fixed onto a solid surface.

Torr A non-SI unit of pressure with the ratio of 760 to 1 standard atmosphere, chosen to be roughly equal to the fluid pressure exerted by a millimeter of mercury. For example, a pressure of 1 torr is approximately equal to 1 mm of mercury.

Total body water (TBW) Any of various estimates of the water content of the human body, taking into consideration the person's height, weight, and age.

Total ion chromatogram (TIC) The sum of all ions produced displayed as a function of time.

Total parenteral nutrition (TPN) The practice of feeding a person intravenously, circumventing the gut.

Total quality management (TQM) A management philosophy and approach that focuses on processes and their improvement as the means to satisfy customer needs and requirements; a quality system that is implemented to ensure quality.

Total testing process A broad definition of the laboratory testing and reporting process that includes preanalytical, analytical, and postanalytical phases.

Toxic epidermal necrolysis (TEN) A rare condition that causes large portions of the epidermis (the skin's outermost layer) to detach from the layers of skin below.

Toxic metals Metals that are elements with high molecular weight and generally toxic in low concentrations to plant and animal life. Note: The International Union of Pure and Applied Chemistry (IUPAC) considers the term "heavy metal" to be both meaningless and misleading and recommends that it no longer be used.

Toxic multinodular goiter A condition in which the thyroid gland contains multiple lumps (nodules) that are overactive and that produce excess thyroid hormones. Also known as Parry disease and Plummer disease.

Toxic nephropathy Kidney damage caused by the effects of a nephrotoxin.

Toxidrome A syndrome caused by a dangerous concentration of toxins in the body.

Toxins Poisonous substances that are produced by living cells or organisms and are capable of causing disease when introduced into the body tissues and are often capable of inducing neutralizing antibodies or antitoxins.

Trace elements Inorganic molecules found in human and animal tissues in milligram per kilogram amounts or less.

Traceability In relation to analytical methods, a concept based on a chain of comparisons of measurements that lead to a known reference value done to ensure reasonable agreement between measurements of routine methods.

Transcription The process of transferring sequence information from the gene regions of DNA to a messenger RNA molecule.

Transcription mediated amplification (TMA) An amplification method that uses RNA polymerase and reverse transcriptase to produce an RNA amplicon from a target nucleic acid. TMA can use either RNA or single-stranded DNA as a template.

Transcriptome The set of all RNA molecules, including (1) messenger RNA (mRNA), (2) ribosomal RNA (rRNA), (3) transfer RNA (tRNA), and (4) other non-coding RNAs produced in one or a population of cells.

Transducing element A component of a point-of-care testing device such as a chemical indicator or a binding molecule that recognizes the analyte of interest and produces an electrical or optical signal.

Transferability or Transference The adoption by a laboratory of previously established reference intervals established elsewhere. Procedures for validation of reference intervals must be completed by the adopting laboratory prior to the use of the transferred RI to ensure that they are appropriate to the laboratory's patient population and laboratory methods.

Transferrin A beta globulin that carries iron in the blood.

Translation The process whereby an mRNA sequence forms an amino acid sequence with the help of tRNA and eventual enzymatic peptide bond formation between amino acids to synthesize polypeptides; translation occurs on cytoplasmic ribosomes.

Transmittance The intensity of a transmitted light beam divided by the intensity of an incident (incoming) light beam passed through a square cell containing a solution of a compound that absorbs light at a specific wavelength stated as T = I/I0; when compared with a reference cell, the transmitted light is divided by the incident light (T = I/IR). A reference cell is used to set an arbitrary value of 100 which corresponds to 100% transmittance.

Transposon A mobile genetic element that can delete and insert itself variably into the genome.

Transthyretin (TTR) A protein found in serum and cerebrospinal fluid that binds to and transports thyroxine (T4). TTR complexes with retinol binding protein (RBP) to prevent its loss through the glomerulus by filtration. Was once called prealbumin, because it travels faster than albumin on electrophoresis gels.

Triglyceride A glycerol ester consisting of three molecules of fatty acid esterified to glycerol and constituting 95% of tissue storage fat.

Triiodothyronine (T_3) The biologically active form of thyroid hormone formed primarily outside of the thyroid gland by the peripheral deiodination of thyroxine (T_4). Has three iodine molecules attached to its molecular structure (L-3,5,3′-triiodothyronine).

Triploidy A condition characterized by the individual having three times the haploid number of chromosomes in the cell nucleus.

Trisomy 18 (Edwards syndrome) A genetic disorder caused by the presence of all or part of an extra 18th chromosome (trisomy: three chromosomes).

Trophoblasts The outermost layer of cells of the blastocyst that attaches the fertilized ovum to the uterine wall and serves as a nutritive pathway for the embryo.

Trough concentration The lowest concentration achieved just before the next dose.

Trueness A qualitative term that describes the closeness of agreement between the average value obtained from a large series of results of measurements and a true value.

Tumor marker A substance produced by a tumor found in blood, body fluids, or tissue that may be used to predict the presence and size of the tumor and monitor its response to therapy.

Tumor-suppressor gene A gene involved in the regulation of cellular growth; loss of a tumor-suppressor gene has the potential to allow autonomous growth.

Turbidimetry The detection and measurement of a decrease in intensity of an incident beam of light as it passes through a solution of particles.

Turnaround time (TAT) T e time between when a test is ordered or a specimen is submitted for analysis and when the test results are reported.

Turner syndrome A chromosomal disorder affecting females wherein one of the two X-chromosomes is defective or completely absent.

Type 1 diabetes mellitus (T1DM) One of the two major types of diabetes mellitus. It is an autoimmune disease that results in the destruction of beta cells of the pancreas, leading to loss of the ability to secrete insulin. Also called insulin-dependent diabetes, type 1A diabetes.

Type 2 diabetes mellitus (T2DM) One of the two major types of diabetes mellitus, characterized by peak age of onset between 50 and 60 years.

Tyrosinemia A genetic disorder involving the metabolism of the tyrosine. Affected individuals have high concentrations of tyrosine in blood (hypertyrosinemia) and urine (tyrosinuria).

Ulcerative colitis Recurrent inflammatory disease of the large bowel that involves the rectum and spreads to involve a variable amount of colon. Ulcerative colitis, like Crohn disease, is a form of inflammatory bowel disease (IBD).

Ultratrace elements Inorganic molecules found in human and animal tissues in microgram per kilogram amounts or less.

Umbilical cord A flexible cordlike structure containing blood vessels and attaching a human or other mammalian fetus to the placenta during gestation.

Uncertainty A parameter characterizing the range of values within which the value of the quantity being measured is expected to lie.

Unconjugated bilirubin Free bilirubin that has not been conjugated with glucuronic acid.

Universal Precautions Approach to infection control that treats all human blood and certain human body fluids as if they were known to be infectious for bloodborne pathogens.

Unstable angina An angina that occurs unpredictably or suddenly increases in severity or frequency.

Upregulation A process that results in an increase in the number of receptors on the surface of target cells, making the cells more sensitive to a hormone or another agent. Downregulation is an decrease in the number of receptors on the surface of target cells.

Urea T e major nitrogen-containing metabolic product of protein catabolism in humans.

Urea cycle disorder Any disorder in which the body is unable to excrete waste nitrogen–ammonia, resulting in mental and behavioral dysfunction, coma, and death.

Urease methods Enzymatic assays that initially involve the hydrolysis of urea by urease to generate ammonia, which is quantified by a variety of methods.

Uremia An excess in the blood of urea, creatinine, and other nitrogenous end products of protein and amino acid metabolism; also referred to as azotemia.

Uremic syndrome T e spectrum of symptoms accompanying uremia.

Uric acid A nitrogenous compound derived from the catabolism of purine nucleosides.

Uricase methods A group of enzymatic assays that initially involve oxidation of uric acid by uricase to eventually produce a chromogen that is spectrophotometrically measured to determine uric acid concentration.

Uridine 5′-diphosphate (UDP)-glucuronosyltransferase (UGT) A family of metabolic enzymes that conjugate compounds with glucuronide molecules.

Urobilinogen A colorless compound formed in the intestines by the reduction of bilirubin.

Uroporphyrin A porphyrin with four acetic acid and four propionic acid sidechains attached to the tetrapyrrole backbone.

Vanillylmandelic acid (VMA) T e main end-product of norepinephrine and epinephrine metabolism excreted in the urine; formed primarily in the liver from oxidation of methoxyhydroxyphenylglycol.

Variable-number tandem repeats (VNTRs) Repeated segments of DNA that are 14 to 500 bases long. Also known as minisatellites.

Variation A change in DNA sequence. It may be benign or may cause disease.

Varices Enlarged and tortuous veins, most commonly found in the esophagus (termed esophageal varices).

Variegate porphyria (VP) An autosomal dominant hepatic porphyria due to mutation in the PPOX gene (locus: 1q22), which encodes protoporphyrinogen oxidase.

Vasoactive intestinal polypeptide (VIP) A peptide of 28 amino acids found in the central and peripheral nervous systems where it acts as a neurotransmitter. It is located in the enteric nerves in the gut. It relaxes smooth muscle in the gut and increases water and electrolyte secretion from the gut.

Venipuncture All of the steps involved in obtaining an appropriate and identified blood specimen from an individual's vein.

Venous occlusion Obstruction of the return of venous blood to the heart and distention of the veins; in phlebotomy, this is a temporary blockage caused by application of pressure, usually from a tourniquet.

Ventricles (right and lef) T e two lower chambers of the heart, responsible, respectively, for pumping blood into the lungs via the pulmonary artery and into the systemic circulation via the aorta.

Vernix caseosa A white cheese-like protective material that covers the skin of a fetus.

Viral hepatitis Liver inflammation caused by viruses. Specific hepatitis viruses have been labeled A, B, C, D, and E.

Viral load T e measurement of the amount of virus in the blood. It is expressed as the copies of virus per milliliter of body fluid and used to guide treatment decisions and monitor response to treatment.

Virilization T e induction or development of male secondary sex characteristics; especially the induction of such changes in the female.

Virtual karyotyping A technique used to analyze a short sequence of DNA from specific loci all over a genome to obtain information that reflects a karyotype.

Vitamer Term used to describe any of a number of compounds that possess a given vitamin activity.

Vitamin An essential organic micronutrient that must be supplied exogenously and in many cases is the precursor to a metabolically derived coenzyme.

Vitamin D Fat-soluble vitamin produced by skin upon exposure to sunlight (vitamin D3, also called cholecalciferol) or adsorbed from foods that contain it (vitamin D2 or ergocalcaciferol); deficiency causes rickets in children and osteomalacia in adults.

Voltammetry An electrolytic electrochemical process in which a specific oxidation or reduction reaction occurs at the surface of the working electrode; it is the charge transfer at this interface (current flow) that provides analytical information.

Waived test A test that (1) employs methodologies that are so simple and accurate as to render the likelihood of erroneous results negligible; (2) poses no reasonable risk of harm to the patient if the test is performed incorrectly; and (3) has been cleared by the Food and Drug Administration for home use.

Waldenström's macroglobulinemia A chronic cancer of the immune system characterized by hyperviscosity, or thickening, of the blood.

Water homeostasis The body process that maintains a balance of water intake and output.

Waterhouse-Friderichsen syndrome Adrenal gland failure caused by bleeding into the adrenal gland; it is a fulminating complication of bacterial infections, notably meningococcemia; characterized by sudden onset and short course, cyanosis with petechial hemorrhages of the skin and mucous membranes, fever, and hypotension that can lead to shock and coma.

Wavelength A characteristic of electromagnetic radiation; the distance between two wave crests that is measured in nanometers.

Western blotting Membrane-based assay in which proteins are separated by electrophoresis, which is followed by transfer to a membrane and probing with a labeled antibody.

Westgard multirules A series of control rules used to interpret quality control data.

Whipple's triad A collection of three criteria suggesting a patient's symptoms result from hypoglycemia.

WHO World Health Organization.

Whole genome amplification (WGA) A non-specific amplification technique that produces an amplified product that represents the initial starting material (whole genome).

Wick flow Movement of water from the buffer reservoirs toward the center of an electrophoresis gel or strip to replace water lost by evaporation.

Wilson disease An autosomal recessive disorder associated with excessive quantities of copper in the tissue, particularly the liver and central nervous system.

Workstation A clinical laboratory workstation dedicated to a defined task and containing appropriate laboratory instrumentation to carry out that task.

Xenobiotics Chemical substances foreign to the biological system. They include naturally occurring compounds, drugs, environmental agents, carcinogens, insecticides, etc.

X-linked hypophosphatemia A form of familial hypophosphatemic rickets, with X-linked dominant inheritance.

X-linked protoporphyria A rare genetic disorder characterized by an abnormal sensitivity to the sun (photosensitivity).

Yolk sac A membranous sac attached to an embryo that provides early nourishment in the form of yolk in many animals, including humans where it functions as the circulatory system before internal circulation begins.

Zero-order kinetics In an enzymatic reaction, when the reaction rate is constant at maximum value, the reaction rate depends only on enzyme concentration and is independent of substrate concentration; the rate of reaction is proportional to the zero power of the substrate concentration.

Zinc finger A finger-shaped fold in a protein that is created by the binding of specific amino acids in the protein to a zinc atom. Zinc-finger proteins regulate the expression of genes as well as nucleic acid recognition, reverse transcription, and virus assembly.

Zinc protoporphyrin (ZPP) A normal but minor by-product of heme biosynthesis found in the red blood cell; when insufficient Fe^{2+} is available for heme biosynthesis, increased ZPP is formed.

Zollinger-Ellison (Z-E) syndrome A condition resulting from a gastrin-producing tumor (gastrinoma) that results in an overproduction of gastric acid, leading to ulceration of the esophagus, stomach, duodenum, and jejunum, and causing hypergastrinemia, diarrhea, and steatorrhea.

Zona fasciculata The thick middle layer of the adrenal cortex that contains large lipid-laden cells. It is the major source of glucocorticoids and, to a lesser extent, adrenal androgens.

Zona glomerulosa The thin outer layer of the adrenal cortex. It is the source of mineralocorticoids.

Zona reticularis The inner layer of the adrenal cortex. Its cells resemble those of the zona fasciculata, except they contain less lipid. The zona reticularis is the major source of adrenal androgens and produces glucocorticoids to a lesser degree.

Zygote The fertilized ovum or diploid cell resulting from the fusion of two haploid gametes.

Intrinsic pathway, 309
Inulin, 659–660

Iodine
deficiency of, 814
dietary, 809
hyperthyroidism induced by, 817
Iodoacetate, 77
Iodothyronine deiodinase, 491–492
Iohexol, 660
Ion exchange, 112
Ion-exchange chromatography, 187–188, 187f
Ionic concentration, 158
Ionic strength, 173
Ionization constants, 290t
Ionophores, 156f
Ion-pair chromatography, 188
Ion-selective electrodes
calcium measurements using, 747
chloride measurement using, 416
description of, 154–157, 262
direct potentiometry by, 158
polymer membrane-type, 164
potassium measurements using, 415
potentiometric cell, 152f
sodium measurements using, 415, 416f
Ion-selective electrolytes, 413–414
Ion-selective membrane, 154
Ion-suppression chromatography, 188
Iontophoresis
description of, 172
pilocarpine, 418
Iron
deficiency of, 509–510
description of, 600
distribution of, 508–509
homeostasis of, 509
measurement of, 511–513
metabolic acidosis associated with, 694
overload of, 510–511
reference intervals for, 952t
serum, 511–513
tissue, 509
transport of, 509
Irreversible inhibition, 228–229
Ischemia
definition of, 633–634
metabolic acidosis and, 694
Ischemic hepatitis, 715
Islet cell cytoplasmic antibodies, 616
ISO 9000, 104
Isocoproporphyrin, 524t
Isoelectric focusing, 173
Isoelectric focusing electrophoresis, 176–177, 176f, 179
Isoelectric point, 172, 288–290
Isoenzymes, 219–223
alkaline phosphatase, 327–328
creatine kinase, 320–322, 321f
definition of, 219
distribution of, 221–222
embryogenesis-related changes in, 222
hybrid, 220
immunochemical analysis methods, 234
measurement of, 234
multilocus, 222
origin of, 221f
Isoforms
definition of, 220
measurement of, 234
Isoimmunization. See Hemolytic disease of the newborn
Isoleucine, 288t–289t
Isoniazid, 694, 982t–983t
Isopropanol, 567
Isoprostanes, 648
Isosmotic hyponatremia, 684
Isotope-dilution mass spectrometry
creatinine measurement using, 367–368
description of, 204
Ito cells, 703
Itraconazole, 982t–983t
IVDMIA, 354

J

Jaffe reaction, 365–366, 952t
Jaundice, 515

Ultraviolet light
  absorbance of, 294
  description of, 131, 131t
Ultraviolet oxidation, 112
Ultraviolet spectrophotometry, 924
Unbound free fatty acid, 649
Uncertainty, 28–30
  definition of, 7
  direct assessment of, 29–30
  indirect evaluation of, 30
  standard, 29
Uncompetitive inhibition, 228
Unconjugated bilirubin, 515
Unconjugated estriol, 865–866
Unconjugated hyperbilirubinemia, 704–705
Unit operations, 255, 255b
Units of measurement, 109–111
  metric system, 109, 110t
  SI units, 109–110, 109t
  standardized reporting of test results, 110–111
Universal precautions, 123–124
Unsaturated iron binding capacity, 306
Unstable angina, 635–636
Urea, 368–370
  biochemistry of, 369
  clinical significance of, 369
  cycle pathway of, 369f
  definition of, 670–671
  excretion of, 369
  hepatic synthesis of, 706
  measurement methods for, 369–370
  physiology of, 369
  plasma concentration of, 369
  reference intervals for, 370
  uremic syndrome and, 670–671
Urea cycle disorders, 878, 879f
Uremia, 369, 670, 693
Uremic syndrome, 670–671
Uric acid, 370–374
  biochemistry of, 370
  clinical significance of, 370–373
  description of, 370
  diets and, 374
  disorders of
    gout, 372–373
    hyperuricemia, 372–374, 372b
    hypouricemia, 373
  kidney stones caused by, 373
  measurement methods, 373–374
    high-performance liquid chromatography, 374
    phosphotungstic acid, 373
    uricase methods, 373–374
  physiology of, 370
  reference intervals for, 374, 952t
  renal handling of, 370
Uricase, 373–374, 952t
Uridine diphosphate–glucuronyltransferase, 514–515, 895
Urinalysis, 663–665
Urinary free cortisol, 788
Urinary prealbumin, 302

Urinary proteins
characteristics of, 662t
description of, 315
electrophoretic separation of, 297
Urinary thromboxane, 649
Urination, 655–656
Urine
albumin in, 629–630
automated analyzers for analysis of, 269
bilirubin levels in, 519, 704–705
catecholamines, 455
chorionic gonadotropin in, 856
dopamine in, 448, 448f
ethanol measurements, 568
formation of, 656
glucose in
measurement methods, 385
strip tests for, 385
hemoglobin in, 665
ketone bodies in, 625
17-ketosteroids in, 845
metanephrines in, 454–455
norepinephrine in, 448
porphyrins in, 534
in pregnancy, 86–87
protein excretion in, 662–663
riboflavin concentration, 472–473
sodium excretion in, 414, 683
zinc levels, 496
Urine dipsticks, 275, 276t
Urine osmolality, 420–421
Urine specimen, 78–79
catheter-acquired, 78
clean timed, 78
collection of, 574–575
for drug testing, 574–575
preservatives added to, 79
refrigeration of, 79
sulfamic acid added to, 79
timed, 78–79
Urobilinogens, 515, 704
UROD, 529
Urokinase-plasminogen activator, 346–347
Uroporphyrin, 524, 524t
Uroporphyrinogen decarboxylase, 526
Uroporphyrinogen-III synthase, 525

V

Valine, 288t–289t
Valinomycin, 415
Valium. See Diazepam
Valproic acid, 545t, 547–548, 982t–983t
Van der Waals-London dipole-dipole interactions, 239
Vanadium, 497–498, 605–606
Vancomycin, 549t, 550, 982t–983t
Vanillylmandelic acid, 445–446, 452, 455–457, 952t
Vapor pressure, 420
Vapor pressure osmometer, 421
Vaporization, 126
Variable-number tandem repeats, 947
Variance component analysis, 13
Varices, 707–708
Variegate porphyria, 527t–528t, 531
Vasoactive intestinal polypeptide, 432t–435t, 727, 728t, 729
Vasopressin, 432t–435t, 779–781
Vegetarianism, 84
Venipuncture, 73–76
illustration of, 75f
order of draw, 75, 75t
patient identification verification before, 73–74
phlebotomist, 74
system for, 75
technique for, 75f, 76
tourniquets for, 74
Venlafaxine, 556t, 982t–983t
Veno-occlusive disease of the liver, 550–551
Ventricles, 633–634
Verification bias, 44
Versed. See Midazolam
Very-low density lipoprotein, 398, 398t, 400
Vigabatrin, 982t–983t
VIPoma, 736–737
Viral genomes, 949
Viral hepatitis
characteristics of, 711–712, 711t
during pregnancy, 857
Viral thyroiditis, 814
Virilization, 839–840
Virtual karyotyping, 935–936
Vitamer, 461–462
Vitamin A
absorption of, 462
characteristics of, 461t, 463t
chemistry of, 461–462
deficiency of, 464
dietary sources of, 462
functions of, 462
intake of, 464
laboratory assessment of, 464
reference intervals for, 464, 952t
structure of, 463f
toxicity, 464
in visual cycle, 463f
Vitamin B_6. See Pyridoxine
Vitamin B_{12}
bacterial metabolism of, 734
characteristics of, 461t, 463t
chemistry of, 473
deficiency of, 474
definition of, 473
dietary sources of, 473
functions of, 473–474
intake of, 474
laboratory assessment of, 474–475
reference intervals, 475
Vitamin C, 461t, 463t, 475–476, 952t
Vitamin D
assays for, 758
biochemistry of, 755–756
characteristics of, 461t, 463t, 465
cholecalciferol, 755–756, 756f
deficiency of, 326, 765
description of, 743
1,25-dihydroxyvitamin D, 757b, 758–759
measurement of, 758–759
metabolism of, 756, 757f
metabolites of, 755–756, 757t, 758–759
reference intervals, 759
sources of, 755
Vitamin D-binding protein, 756
Vitamin D-resistant rickets, 766
Vitamin E
absorption of, 465
characteristics of, 461t, 463t
chemistry of, 465
daily requirements, 465
deficiency of, 465
dietary sources of, 465
functions of, 465
intake of, 465
reference intervals for, 466, 952t
toxicity, 465–466
Vitamin K, 310
absorption of, 467
characteristics of, 461t, 463t
chemistry of, 466–467
deficiency of, 467–468
dietary sources of, 467
functions of, 467
intake of, 467
laboratory assessment of, 468
reference intervals, 468, 952t
toxicity, 468
Vitamin K epoxide reductase complex 1, 896
Volatile alcohols, 569
Volatiles, 126

Voltammetry, 158–162
applications of, 160–162
concepts of, 158–160
Voltammogram, 159
Volumetric flasks, 116–117, 116f
Volumetric pipettes, 114, 114f
von Hippel-Lindau syndrome, 450
von Recklinghausen disease. See Neurofibromatosis type 1
Voriconazole, 549t, 550, 982t–983t

W

Waldenström's macroglobulinemia, 313
Wall-coated open tubular columns, 191
Warfarin, 896, 982t–983t
Water
body. See Body water
homeostasis of, 413
metabolism of, 436
Waterhouse-Friderichsen syndrome, 798
Watery diarrhea hypokalemia achlorhydria, 736–737
Weak acids, 119
Weighing, 118
Weighted Deming regression analysis, 27f, 27t
Werner-Morrison syndrome, 736–737
Wernicke-Korsakoff syndrome, 469
Wescor Macroduct Sweat-Chek, 419
Western blotting
description of, 177
HIV-1 antibody detection using, 242, 242f
Westgard multirule chart, 99–100, 100f
Whipple's triad, 381

IUPAC Periodic Table of the Elements

1																	18
1 **H** hydrogen [1.007, 1.009]	2		Key: atomic number **Symbol** **name** standard atomic weight									13	14	15	16	17	2 **He** helium 4.003
3 **Li** lithium [6.938, 6.997]	4 **Be** beryllium 9.012											5 **B** boron [10.80, 10.83]	6 **C** carbon [12.00, 12.02]	7 **N** nitrogen [14.00, 14.01]	8 **O** oxygen [15.99, 16.00]	9 **F** fluorine 19.00	10 **Ne** neon 20.18
11 **Na** sodium 22.99	12 **Mg** magnesium [24.30, 24.31]	3	4	5	6	7	8	9	10	11	12	13 **Al** aluminium 26.98	14 **Si** silicon [28.08, 28.09]	15 **P** phosphorus 30.97	16 **S** sulfur [32.05, 32.08]	17 **Cl** chlorine [35.44, 35.46]	18 **Ar** argon 39.95
19 **K** potassium 39.10	20 **Ca** calcium 40.08	21 **Sc** scandium 44.96	22 **Ti** titanium 47.87	23 **V** vanadium 50.94	24 **Cr** chromium 52.00	25 **Mn** manganese 54.94	26 **Fe** iron 55.85	27 **Co** cobalt 58.93	28 **Ni** nickel 58.69	29 **Cu** copper 63.55	30 **Zn** zinc 65.38(2)	31 **Ga** gallium 69.72	32 **Ge** germanium 72.63	33 **As** arsenic 74.92	34 **Se** selenium 78.96(3)	35 **Br** bromine [79.90, 79.91]	36 **Kr** krypton 83.80
37 **Rb** rubidium 85.47	38 **Sr** strontium 87.62	39 **Y** yttrium 88.91	40 **Zr** zirconium 91.22	41 **Nb** niobium 92.91	42 **Mo** molybdenum 95.96(2)	43 **Tc** technetium	44 **Ru** ruthenium 101.1	45 **Rh** rhodium 102.9	46 **Pd** palladium 106.4	47 **Ag** silver 107.9	48 **Cd** cadmium 112.4	49 **In** indium 114.8	50 **Sn** tin 118.7	51 **Sb** antimony 121.8	52 **Te** tellurium 127.6	53 **I** iodine 126.9	54 **Xe** xenon 131.3
55 **Cs** caesium 132.9	56 **Ba** barium 137.3	57-71 lanthanoids	72 **Hf** hafnium 178.5	73 **Ta** tantalum 180.9	74 **W** tungsten 183.8	75 **Re** rhenium 186.2	76 **Os** osmium 190.2	77 **Ir** iridium 192.2	78 **Pt** platinum 195.1	79 **Au** gold 197.0	80 **Hg** mercury 200.6	81 **Tl** thallium [204.3, 204.4]	82 **Pb** lead 207.2	83 **Bi** bismuth 209.0	84 **Po** polonium	85 **At** astatine	86 **Rn** radon
87 **Fr** francium	88 **Ra** radium	89-103 actinoids	104 **Rf** rutherfordium	105 **Db** dubnium	106 **Sg** seaborgium	107 **Bh** bohrium	108 **Hs** hassium	109 **Mt** meitnerium	110 **Ds** darmstadtium	111 **Rg** roentgenium	112 **Cn** copernicium		114 **Fl** flerovium		116 **Lv** livermorium		

57 **La** lanthanum 138.9	58 **Ce** cerium 140.1	59 **Pr** praseodymium 140.9	60 **Nd** neodymium 144.2	61 **Pm** promethium	62 **Sm** samarium 150.4	63 **Eu** europium 152.0	64 **Gd** gadolinium 157.3	65 **Tb** terbium 158.9	66 **Dy** dysprosium 162.5	67 **Ho** holmium 164.9	68 **Er** erbium 167.3	69 **Tm** thulium 168.9	70 **Yb** ytterbium 173.1	71 **Lu** lutetium 175.0

89 **Ac** actinium	90 **Th** thorium 232.0	91 **Pa** protactinium 231.0	92 **U** uranium 238.0	93 **Np** neptunium	94 **Pu** plutonium	95 **Am** americium	96 **Cm** curium	97 **Bk** berkelium	98 **Cf** californium	99 **Es** einsteinium	100 **Fm** fermium	101 **Md** mendelevium	102 **No** nobelium	103 **Lr** lawrencium

INTERNATIONAL UNION OF
PURE AND APPLIED CHEMISTRY

Notes

- IUPAC 2011 Standard atomic weights abridged to four significant digits (Table 4 published in Pure Appl. Chem. 2013;85:1047-78. http://dx.doi.org/10.1351/PAC-REP-13-03-02. The uncertainty in the last digit of the standard atomic weight value is listed in parentheses following the value. In the absence of parentheses, the uncertainty is one in that last digit. An interval in square brackets provides the lower and upper bounds of the standard atomic weight for that element. No values are listed for elements which lack isotopes with a characteristic isotopic abundance in natural terrestrial samples. See PAC for more details.
- "Aluminum" and "cesium" are commonly used alternative spellings for "aluminium" and "caesium."
- Claims for the discovery of all the remaining elements in the last row of the Table, namely elements with atomic numbers 113, 115, 117 and 118, and for which no assignments have yet been made, are being considered by a IUPAC and IUPAP Joint Working Party.

For updates to this table, see iupac.org/reports/periodic_table/. This version is dated May 1, 2013.
